On nitrates,
but angina still
strikes...

After a nitrate, add ISOPTIN®
(verapamil HCl/Knoll)

To protect your patients, as well as their quality of life, add Isoptin instead of a beta blocker.

First, Isoptin not only reduces myocardial oxygen demand by reducing peripheral resistance, but also increases coronary perfusion by preventing coronary vasospasm and dilating coronary arteries — both normal and stenotic. These are antianginal actions that no beta blocker can provide.

Second, Isoptin spares patients the beta-blocker side effects that may compromise the quality of life.

With Isoptin, fatigue, bradycardia and mental depression are rare. Unlike beta blockers, Isoptin can safely be given to patients with asthma, COPD, diabetes or peripheral vascular disease. Serious adverse reactions with Isoptin are rare at recommended doses; the single most common side effect is constipation (6.3%).

Cardiovascular contraindications to the use of Isoptin are similar to those of beta blockers: severe left ventricular dysfunction, hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no artificial pacemaker is present) and second- or third-degree AV block.

So, the next time a nitrate is not enough, add Isoptin... for more comprehensive antianginal protection without side effects which may cramp an active life style.

ISOPTIN. Added antianginal protection without beta-blocker side effects.

Please see brief summary on following page.

ISOPTIN®
(verapamil HCl/Knoll)
80 mg and 120 mg scored, film-coated tablets

Contraindications: Severe left ventricular dysfunction (see *Warnings),* hypotension (systolic pressure < 90 mm Hg) or cardiogenic shock, sick sinus syndrome (except in patients with a functioning artificial ventricular pacemaker), 2nd- or 3rd-degree AV block. **Warnings:** ISOPTIN should be avoided in patients with severe left ventricular dysfunction (e.g., ejection fraction < 30% or moderate to severe symptoms of cardiac failure) and in patients with any degree of ventricular dysfunction if they are receiving a beta blocker. (See *Precautions.)* Patients with milder ventricular dysfunction should, if possible, be controlled with optimum doses of digitalis and/or diuretics before ISOPTIN is used. (Note interactions with digoxin under *Precautions.*) ISOPTIN may occasionally produce hypotension (usually asymptomatic, orthostatic, mild and controlled by decrease in ISOPTIN dose). Elevations of transaminases with and without concomitant elevations in alkaline phosphatase and bilirubin have been reported. Such elevations may disappear even with continued treatment; however, four cases of hepatocellular injury by verapamil have been proven by rechallenge. Periodic monitoring of liver function is prudent during verapamil therapy. Patients with atrial flutter or fibrillation and an accessory AV pathway (e.g. W-P-W or L-G-L syndromes) may develop increased antegrade conduction across the aberrant pathway bypassing the AV node, producing a very rapid ventricular response after receiving ISOPTIN (or digitalis). Treatment is usually D.C.-cardioversion, which has been used safely and effectively after ISOPTIN. Because of verapamil's effect on AV conduction and the SA node, 1° AV block and transient bradycardia may occur. High grade block, however, has been infrequently observed. Marked 1° or progressive 2° or 3° AV block requires a dosage reduction or, rarely, discontinuation and institution of appropriate therapy depending upon the clinical situation. Patients with hypertrophic cardiomyopathy (IHSS) received verapamil in doses up to 720 mg/day. It must be appreciated that this group of patients had a serious disease with a high mortality rate and that most were refractory or intolerant to propranolol. A variety of serious adverse effects were seen in this group of patients including sinus bradycardia, 2° AV block, sinus arrest, pulmonary edema and/or severe hypotension. Most adverse effects responded well to dose reduction and only rarely was verapamil discontinued. **Precautions:** ISOPTIN should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of excessive pharmacologic effects. Studies in a small number of patients suggest that concomitant use of ISOPTIN and beta blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, ISOPTIN should be used alone, if possible. If combined therapy is used, close surveillance of vital signs and clinical status should be carried out. Combined therapy with ISOPTIN and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function. Chronic ISOPTIN treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when ISOPTIN is given, and the patients should be carefully monitored to avoid over- or under-digitalization. ISOPTIN may have an additive effect on lowering blood pressure in patients receiving oral antihypertensive agents. Disopyramide should not be given within 48 hours before or 24 hours after ISOPTIN administration. Until further data are obtained, combined ISOPTIN and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Clinical experience with the concomitant use of ISOPTIN and short- and long-acting nitrates suggest beneficial interaction without undesirable drug interactions. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. *Pregnancy Category C*: There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during ISOPTIN use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd degree (0.8%), bradycardia: HR < 50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%), elevations of liver enzymes have been reported. (See *Warnings.*) The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: ecchymosis, bruising, gynecomastia, psychotic symptoms, confusion, paresthesia, insomnia, somnolence, equilibrium disorder, blurred vision, syncope, muscle cramp, shakiness, claudication, hair loss, macules, spotty menstruation. **How Supplied:** ISOPTIN (verapamil HCl) is supplied in round, scored, film-coated tablets containing either 80 mg or 120 mg of verapamil hydrochloride and embossed with "ISOPTIN 80" or "ISOPTIN 120" on one side and with "KNOLL" on the reverse side. Revised August, 1984. 2385

CARDIOLOGIST

For busy noninvasive and invasive cardiology practice. Medium sized city near resort area. 370-bed, modern, well-equipped hospital. Early partnership possible. Excellent starting salary. Write Box 485, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Cardiologist Wanted—A large Cardiology Practice in a major Northeastern City is seeking a well qualified Cardiologist to join an established Referral Cardiology Practice. The Practice offers well rounded clinical, invasive and non-invasive opportunities, affiliation with a major Medical Center, and a large private Teaching Hospital. Please send letter and curriculum vitae to Reply Box 470, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

CARDIOLOGIST

To join consultative cardiology practice for large referral area. Training in cardiac catheterization, PTCA and noninvasive mandatory. Located in South. Send C.V. and details about your interests to Box 435, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

Cardiologist to practice non-invasive cardiology to join one other cardiologist on staff of 39 M.D. multispecialty and family practice clinic. Attractive income arrangements, association membership possible after one year, pension, profit sharing, extensive fringe benefits. Reply to Box 475, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

CARDIOLOGIST: Director of noninvasive testing, preferably with nuclear license, with training in invasive procedures to join busy invasive/noninvasive practice serving 700 beds. Open heart program, currently doing PTCA and all noninvasives. Midwest city, excellent regional medical center with state of the art diagnostics. High motivation for continuing education, teaching, expanding limits of the practice. Reply to Box 480, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

SUBJECT INDEX: VOLUME 56*

Accessory pathway
Effects of oral amiodarone on rate-dependent changes in refractoriness in patients with Wolff-Parkinson-White syndrome, 863
Simultaneous computer mapping to facilitate intraoperative localization of accessory pathways in patients with Wolff-Parkinson-White syndrome, 571
Spontaneous termination of reciprocating tachycardia owing to interaction of dual atrioventricular nodal pathways in patients with an accessory pathway, 872

Actin

Atrial septal aneurysm: echopolycardiographic study, 653
Detection of intracardiac shunt flow in atrial septal defect using a real-time two-dimensional color-coded Doppler flow imaging system and comparison with contrast two-dimensional echocardiography, 347
Extravascular lung water in children immediately after operative closure of either isolated atrial septal defect or ventricular septal defect, 536

Atrioventricular block
Electrophysiologic evaluation of the cardiac conduction system and its autonomic regulation in familial amyloid polyneuropathy, 647

Atrioventricular node
Atrioventricular nodal supraventricular tachycardia, 193
Spontaneous termination of reciprocating tachycardia owing to interaction of dual atrioventricular nodal pathways in patients with an accessory pathway, 872

Atrioventricular pathway
Spontaneous termination of reciprocating tachycardia owing to interaction of dual atrioventricular nodal pathways in patients with an accessory pathway, 872

Atropine
Autonomic dependence of ventriculoatrial conduction, 285

Auscultation
Auscultation, M-mode echocardiography and pulsed Doppler echocardiography compared with angiography for diagnosis of chronic aortic regurgitation, 811

Balloon angioplasty
Nd-YAG laser fusion of human atheromatous plaque-arterial wall separations in vitro, 953

Balloon dilatation
Balloon dilatation catheter size selection (LE), 911

Balloon septostomy
Infusion of blood from pericardial sac into femoral vein: a technique for survival until operative closure of a cardiac perforation during balloon septostomy, 494

Bedrest
Cardiovascular deconditioning produced by 20 hours of bedrest with head-down tilt (−5°) in middle-aged healthy men, 634

Bernoulli equation
In vitro study of the pressure-velocity relation across stenotic orifices, 465

Beta-adrenergic blockade
Acute hemodynamic and electrophysiologic effects of propranolol in patients receiving diltiazem, 47
Beta-adrenergic stimulation reverses postischemic myocardial dysfunction without producing subsequent functional deterioration, 964
Effects of atenolol on exercise capacity in patients with mitral stenosis with sinus rhythm, 598
Efficacy of carvedilol (BM14,190), a new beta-blocking drug with vasodilating properties, in exercise-induced ischemia, 35
Hypokalemia from $beta_2$-receptor stimulation by circulating epinephrine, 3D
Prevention of epinephrine-induced hypokalemia by nonselective beta blockers, 10D
Single and combined therapy for systemic hypertension with propranolol, hydralazine and hydrochlorothiazide: hemodynamic and neuroendocrine mechanisms of action, 315

Bioprostheses
See also Valve prostheses
Doppler hemodynamic evaluation of prosthetic (Starr-Edwards and Björk-Shiley) and bioprosthetic (Hancock and Carpentier-Edwards) cardiac valves, 325
Quantitative anatomic analysis of "stent creep" of explanted Hancock standard porcine bioprostheses used for cardiac valve replacement, 110

Björk-Shiley prosthesis
Doppler hemodynamic evaluation of prosthetic (Starr-Edwards and Björk-Shiley) and bioprosthetic (Hancock and Carpentier-Edwards) cardiac valves, 325
Regurgitation of normal Björk-Shiley prosthetic valves in the aortic valve position, 489

Blood flow
Continuous determination of regional myocardial blood flow with intracoronary krypton-81m in coronary artery disease, 445
Coronary hemodynamic responses during spontaneous angina in patients with and patients without coronary artery spasm, 41
Coronary vasomotion in angina at rest and effect of sublingual nitroglycerin on coronary blood flow, 484
Dynamic nature of coronary collateral blood flow, 994
Echocardiographic detection of circulating blood in normal canine hearts, 834
Functional significance of transient collaterals during coronary artery spasm, 407
Hemodynamic principles in the control of coronary blood flow, 4E
Systemic, left ventricular and coronary hemodynamic effects of intravenous diltiazem in coronary artery disease, 413

Blood glucose
Relation of hemoglobin A_1 and blood glucose to cardiac function in diabetes mellitus, 642

Blood pressure
See also Hypertension
Circulatory effects of coffee in relation to the pharmacokinetics of caffeine, 958
Effects of exercise on blood pressure, plasma catecholamines, potassium and the electrocardiogram after diuretic and neural-blocking therapy for moderate hypertension, 39D

Body posture
Induction and termination of ventricular tachycardia by changing body posture, 800

Brown adipose tissue
Prevalence of brown adipose tissue in chronic congestive heart failure secondary to coronary heart disease, 197

Bucindolol
Bucindolol, 704

Bundle branch block
Exercise-induced left bundle branch block and its relation to coronary artery disease, 892
Exercise-related bundle branch block in children, 796

Caffeine
Circulatory effects of coffee in relation to the pharmacokinetics of caffeine, 958
Effects of caffeine on vascular resistance, cardiac output and myocardial contractility in young men, 119

Calcium antagonists
Acute effects of intravenous nisoldipine on left ventricular function and coronary hemodynamics, 140
Acute hemodynamic and electrophysiologic effects of propranolol in patients receiving diltiazem, 47
Effect of intracoronary verapamil on infarct size in the ischemic, reperfused canine heart: critical importance of the timing of treatment, 672
Efficacy of calcium channel blocker therapy for angina pectoris resulting from small-vessel coronary artery disease and abnormal vasodilator reserve, 242
Nicardipine for angina pectoris at rest and coronary arterial spasm, 232
Systemic, left ventricular and coronary hemodynamic effects of intravenous diltiazem in coronary artery disease, 413

Canine studies
Anatomic and hemodynamic effects of catheter-delivered ablation energies in the ventricle, 373
Beta-adrenergic stimulation reverses postischemic myocardial dysfunction without producing subsequent functional deterioration, 964
Cardiovascular and pharmacokinetic consequences of combined administration of verapamil and propranolol in dogs, 147
Echocardiographic detection of circulating blood in normal canine hearts, 834
Effect of intracoronary verapamil on infarct size in the ischemic, reperfused canine heart: critical importance of the timing of treatment, 672
Effects of repeated brief coronary occlusion on regional left ventricular function and dimension in dogs, 473
Measurement of cardiac output by cine computed tomography, 657
Myocardial kinetics of thallium-201 after stress in normal and perfusion-reduced canine myocardium, 969
Relation of myocardial salvage to size of myocardium at risk in dogs, 974
Sudden death and experimental acute myocardial infarction, 677
The healing process in normal canine arteries and in atherosclerotic monkey arteries after transluminal laser irradiation, 983
Usefulness of a free radical scavenger in preventing doxorubicin-induced heart failure in dogs, 157
Validation of instantaneous pressure gradients measured by continuous-wave Doppler in experimentally induced aortic stenosis, 989

Captopril
Systemic hypertension after cardiac transplantation: effect of cyclosporine on the renin-angiotensin-aldosterone system, 927
Cardiac arrest
Ambulatory electrocardiographic recordings at the time of fatal cardiac arrest, 588
Cardiac catheterization
Interhospital transport of patients with ongoing intraaortic balloon pumping, 59
Localized aortic dissection with rupture into the right atrium: diagnosis by computed tomography and cardiac catheterization, 204
Safety of outpatient cardiac catheterizations, 639
Cardiac neuropathy
Electrophysiologic evaluation of the cardiac conduction system and its autonomic regulation in familial amyloid polyneuropathy, 647
Cardiac output
Analysis of factors affecting the variability of Fick versus indicator dilution measurements of cardiac output, 764
Measurement of cardiac output by cine computed tomography, 657
Measurement of cardiac output during exercise by the thermodilution and direct fick techniques in patients with chronic congestive heart failure, 321
Cardiac tamponade
Coronary artery aneurysm producing right ventricular outflow obstruction, 192
Cardiomyopathy
Arrhythmogenic right ventricular dysplasia in a family, 799
Determinants of prognosis in idiopathic dilated cardiomyopathy as determined by programmed electrical stimulation, 337
Effects of hydralazine on pressure-volume and stress-volume relations in congestive heart failure secondary to idiopathic dilated cardiomyopathy, 690
Electrophysiologic evaluation of the cardiac conduction system and its autonomic regulation in familial amyloid polyneuropathy, 647
Right-axis deviation and anterior wall thallium-201 defect in Becker's muscular dystrophy, 203
Usefulness of a free radical scavenger in preventing doxorubicin-induced heart failure in dogs, 157
Cardiovascular deconditioning
Cardiovascular deconditioning produced by 20 hours of bedrest with head-down tilt (−5°) in middle-aged healthy men, 634
Cardioversion
Anatomic and hemodynamic effects of catheter-delivered ablation energies in the ventricle, 373
Effect of damped sine-wave shocks on catheter dielectric strength, 769
Carvedilol
Efficacy of carvedilol (BM14,190), a new beta-blocking drug with vasodilating properties, in exercise-induced ischemia, 35
Catecholamines
Effect of a benzodiazepine (alprazolam) on plasma epinephrine and norepinephrine levels during exercise stress, 136
Effects of exercise on blood pressure, plasma catecholamines, potassium and the electrocardiogram after diuretic and neural-blocking therapy for moderate hypertension, 39D
Catheters
Anatomic and hemodynamic effects of catheter-delivered ablation energies in the ventricle, 373
Balloon dilatation catheter size selection (LE), 911
Effect of damped sine-wave shocks on catheter dielectric strength, 769
Primary angiographic success rates of percutaneous transluminal coronary angioplasty, 712
Children
Acute hemodynamic effects of nitroprusside in children with isolated mitral regurgitation, 351
Anticoagulation therapy in children with mechanical prosthetic cardiac valves, 533
Assessment of right ventricular outflow tract in children by two-dimensional echocardiography using a new subcostal view. Angiocardiographic and morphologic correlative study, 539
Effect of intense aerobic training on exercise performance in children after surgical repair of tetralogy of Fallot or complete transposition of the great arteries, 816
Exercise-related bundle branch block in children, 796
Extravascular lung water in children immediately after operative closure of either isolated atrial septal defect or ventricular septal defect, 536
Rest and exercise hemodynamics in pulmonary stenosis: comparison of children and adults, 360
Results of balloon valvuloplasty in the treatment of congenital valvar pulmonary stenosis in children, 527
Chlorthalidone
Systolic hypertension in the elderly program (SHEP): antihypertensive efficacy of chlorthalidone, 913
Cholesterol
Factors associated with progression of coronary artery disease in patients with normal or minimally narrowed coronary arteries, 30
Cigarette smoking
Factors associated with progression of coronary artery disease in patients with normal or minimally narrowed coronary arteries, 30
Circulatory shock
Circulatory shock due to ascites and responsive to paracentesis, 500
Cirrhosis
Arrhythmias and left ventricular function in chronic alcoholics with alcoholic cirrhosis, 825
Coarctation
Balloon occlusion angiography in infancy: methods, uses and limitations, 495
Coarctation of the aorta inherited as an autosomal dominant trait, 818
Computerized tomography and ultrasound in the noninvasive evaluation of coarctation of the aorta, 822
Prosthetic repair of coarctation of the aorta with particular reference to Dacron onlay patch grafts and late aneurysm formation, 342
Cocaine
Relation of acute myocardial infarction to cocaine abuse, 794
Coenzyme Q_{10}
Effects of coenzyme Q_{10} on exercise tolerance in chronic stable angina pectoris, 247
Coffee
Circulatory effects of coffee in relation to the pharmacokinetics of caffeine, 958
Cold pressor test
Cold-induced immersion injury (LE), 1007
Different susceptibility to myocardial ischemia provoked by hyperventilation and cold pressor test in exertional and variant angina pectoris, 18
Collateral flow
Collateral flow in patients with acute myocardial infarction, 729
Dynamic nature of coronary collateral blood flow, 994
Evaluation of coronary collateral circulation (LE), 1006
Collateral vessels
Functional significance of transient collaterals during coronary artery spasm, 407
Computer methods
Influence of R-wave amplitude on exercise-induced ST depression: need for a "gain factor" correction when interpreting stress electrocardiograms, 13
Measurement of cardiac output by cine computed tomography, 657
Reproducibility of left ventricular area and volume measurements using a computer endocardial edge-detection algorithm in normal subjects, 947
Conduction
Autonomic dependence of ventriculoatrial conduction, 285
Electrophysiologic evaluation of the cardiac conduction system and its autonomic regulation in familial amyloid polyneuropathy, 647
Congestive heart failure
Acute effects of digoxin on total systemic vascular resistance in congestive heart failure due to dilated cardiomyopathy: a hemodynamic-hormonal study, 896
Comparative vasoactive therapy for heart failure, 19B
Effect of enalapril on ventricular arrhythmias in congestive heart failure, 566
Effects of amrinone on myocardial energetics in severe congestive heart failure, 16B
Effects of hydralazine on pressure-volume and stress-volume relations in congestive heart failure secondary to idiopathic dilated cardiomyopathy, 690
Epidemiology of congestive heart failure, 2A
Hemodynamic and hormonal effects of high-dose transdermal nitroglycerin in patients with chronic congestive heart failure, 555
Immediate effects of milrinone on metabolic and sympathetic responses to exercise in severe congestive heart failure, 93
Intravenous use of amrinone for the treatment of the failing heart, 8B
Measurement of cardiac output during exercise by the thermodilution and direct fick techniques in patients with chronic congestive heart failure, 321
Nitrates for congestive heart failure, 19A
Norepinephrine infusions in congestive heart failure, 802
Pathophysiology of cardiac failure, 3B
Pathophysiology of congestive heart failure, 7A
Pharmacokinetics and pharmacodynamics of milrinone in chronic congestive heart failure, 685

Prevalence of brown adipose tissue in chronic congestive heart failure secondary to coronary heart disease, 197
Spectrum of acute hemodynamic effects of nifedipine in severe congestive heart failure, 560
Sympathetic tone in congestive heart failure (LE), 912

Contractility
Effects of caffeine on vascular resistance, cardiac output and myocardial contractility in young men, 119
Effects of hydralazine on pressure-volume and stress-volume relations in congestive heart failure secondary to idiopathic dilated cardiomyopathy, 690

Contrast angiography
Regional left ventricular wall motion assessment: comparison of two-dimensional echocardiography and radionuclide angiography with contrast angiography in healed myocardial infarction, 8

Contrast media
Detection of intracardiac shunt flow in atrial septal defect using a real-time two-dimensional color-coded Doppler flow imaging system and comparison with contrast two-dimensional echocardiography, 347

Coronary arterial spasm
Nicardipine for angina pectoris at rest and coronary arterial spasm, 232

Coronary arteries
Aspergillus Fumigatus thrombi causing total occlusion of both coronary arterial ostia, all four major epicardial coronary arteries and coronary sinus and associated with purulent pericarditis, 499
Coronary arterial findings after accidental death immediately after successful percutaneous transluminal coronary angioplasty, 794
Coronary bypass using the internal mammary artery, 480
Dynamic nature of coronary collateral blood flow, 994
Factors associated with progression of coronary artery disease in patients with normal or minimally narrowed coronary arteries, 30
Regulation of coronary resistance vessels and large coronary arteries, 16E
Response of normal and diseased epicardial coronary arteries to vasoactive drugs: quantitative arteriographic studies, 23E
Sudden death and experimental acute myocardial infarction, 677

Coronary artery bypass
See also Surgery
Coronary bypass using the internal mammary artery, 480
Life adaptation after percutaneous transluminal coronary angioplasty and coronary artery bypass grafting, 395
Percutaneous transluminal coronary angioplasty after previous coronary artery bypass surgery, 398

Coronary artery disease
See also Coronary heart disease
Acute effects of intravenous nisoldipine on left ventricular function and coronary hemodynamics, 140
A simple device to obtain reproducible echocardiographic apical cross sections, 206
Comparison of exercise electrocardiography and quantitative thallium imaging for one-vessel coronary artery disease, 257
Comparison of stress digital ventriculography, stress thallium scintigraphy, and digital fluoroscopy in the diagnosis of coronary artery disease in subjects without prior myocardial infarction, 434
Continuous determination of regional myocardial blood flow with intracoronary krypton-81m in coronary artery disease, 445
Coronary artery dilation and hemodynamic responses after isosorbide dinitrate therapy in patients with coronary artery disease, 390
Coronary atherosclerosis and antecedent risk factors: pathologic and epidemiologic study in Hisayama, Japan, 62
Determination of the optimal timing for performing digital ventriculography during atrial pacing stress tests in coronary heart disease, 426
Dipyridamole-echocardiography test in effort angina pectoris, 452
Efficacy of calcium channel blocker therapy for angina pectoris resulting from small-vessel coronary artery disease and abnormal vasodilator reserve, 242
Efficacy of combination therapy with mexiletine and a type IA agent for inducible ventricular tachyarrhythmias secondary to coronary artery disease, 277
Electrophysiologic evaluation of the antiarrhythmic effects of N-acetylprocainamide for ventricular tachycardia secondary to coronary artery disease, 877
Exercise-induced left bundle branch block and its relation to coronary artery disease, 892
Factors associated with progression of coronary artery disease in patients with normal or minimally narrowed coronary arteries, 30
Frequency and significance of induced sustained ventricular tachycardia or fibrillation two weeks after acute myocardial infarction, 737
Prospective comparison of Holter monitoring and electrophysiologic study in patients with coronary artery disease and sustained ventricular tachyarrhythmias, 577
Relation between electrocardiographic and scintigraphic location of myocardial ischemia in 1-vessel coronary artery disease, 704
Safety of outpatient cardiac catheterizations, 639
Sequential balloon technique in angioplasty of severe coronary arterial obstructions, 789
Serum fatty acids, apolipoproteins, selenium and vitamin antioxidants and the risk of death from coronary artery disease, 226
Silent myocardial ischemia as a manifestation of asymptomatic coronary artery disease: what is appropriate therapy? 28D
Systemic, left ventricular and coronary hemodynamic effects of intravenous diltiazem in coronary artery disease, 413
Systolic time intervals in coronary heart disease at rest and during exercise (LE), 910
The healing process in normal canine arteries and in atherosclerotic monkey arteries after transluminal laser irradiation, 983

Coronary artery dissection
Variant angina and spontaneous coronary artery dissection, 485

Coronary artery spasm
Coronary hemodynamic responses during spontaneous angina in patients with and patients without coronary artery spasm, 41
Functional significance of transient collaterals during coronary artery spasm, 407

Coronary Artery Surgery Study
Are the findings from the randomized Coronary Artery Surgery Study (CASS) of value in the management of patients soon after acute myocardial infarction? 179

Coronary care unit
Infections in a coronary care unit, 757

Coronary heart disease
See also Coronary artery disease
Anion-channel blockade with alinidine: a specific bradycardiac drug for coronary heart disease without negative inotropic activity? 270
Electropharmacologic testing in sustained ventricular tachycardia associated with coronary heart disease: value of the response to intravenous procainamide in predicting the response to oral procainamide and oral quinidine treatment, 883
Prevalence of brown adipose tissue in chronic congestive heart failure secondary to coronary heart disease, 197
Type A score (Jenkins Activity Survey) and risk of recurrent coronary heart disease in the aspirin myocardial infarction study, 221

Coronary occlusion
Aspergillus Fumigatus thrombi causing total occlusion of both coronary arterial ostia, all four major epicardial coronary arteries and coronary sinus and associated with purulent pericarditis, 499
Coronary artery occlusion seven weeks after angioplasty successfully managed with repeat emergency angioplasty (LE), 1007
Effects of repeated brief coronary occlusion on regional left ventricular function and dimension in dogs, 473

Coronary reperfusion
Beta-adrenergic stimulation reverses postischemic myocardial dysfunction without producing subsequent functional deterioration, 964
Effect of intracoronary verapamil on infarct size in the ischemic, reperfused canine heart: critical importance of the timing of treatment, 672

Coronary resection
Surgical treatment of medically refractory variant angina pectoris: segmental coronary resection with aortocoronary bypass and plexectomy, 792.

Coronary sinus
Aspergillus Fumigatus thrombi causing total occlusion of both coronary arterial ostia, all four major epicardial coronary arteries and coronary sinus and associated with purulent pericarditis, 499

Contrast-enhanced cine computed tomography for diagnosis of right coronary artery to coronary sinus arteriovenous fistula, 997
Coronary sinus occlusion pressure and its relation to intracardiac pressure, 457
Coronary sinus ostium atresia
Angiographic diagnosis of coronary sinus ostium atresia, 996
Creatine kinase
Time course of alpha-1-acid glycoprotein and its relation to myocardial enzymes after acute myocardial infarction, 262
Cyclosporine
Systemic hypertension after cardiac transplantation: effect of cyclosporine on the renin-angiotensin-aldosterone system, 927

Dacron patch grafts
Prosthetic repair of coarctation of the aorta with particular reference to Dacron onlay patch grafts and late aneurysm formation, 342
Death, sudden
Effect of ventricular fibrillation complicating acute myocardial infarction on long-term prognosis: importance of the site of infarction, 384
Frequency and significance of induced sustained ventricular tachycardia or fibrillation two weeks after acute myocardial infarction, 737
Mitral valve prolapse, Wolff-Parkinson-White syndrome, his bundle sclerosis and sudden death, 700
Sudden death and experimental acute myocardial infarction, 677
Defibrotide
Usefulness of defibrotide in protecting ischemic myocardium from early reperfusion damage, 978
Demographic studies
Evaluation of methods of measurement and estimation of left ventricular function after acute myocardial infarction, 753
Diabetes mellitus
Relation of hemoglobin A_1 and blood glucose to cardiac function in diabetes mellitus, 642
Diastole
Doppler evaluation of left ventricular diastolic filling in children with systemic hypertension, 921
Digital studies
Comparison of stress digital ventriculography, stress thallium scintigraphy, and digital fluoroscopy in the diagnosis of coronary artery disease in subjects without prior myocardial infarction, 434
Digital quantification eliminates intraobserver and interobserver variability in the evaluation of coronary artery stenosis, 718
Digoxin
Acute effects of digoxin on total systemic vascular resistance in congestive heart failure due to dilated cardiomyopathy: a hemodynamic-hormonal study, 896
Diltiazem
Acute hemodynamic and electrophysiologic effects of propranolol in patients receiving diltiazem, 47
Effect of diltiazem and ibuprofen on right ventricular hypertrophy in an experimental model of hypoxic pulmonary hypertension, 470
Systemic, left ventricular and coronary hemodynamic effects of intravenous diltiazem in coronary artery disease, 413
Dipyridamole
Dipyridamole-echocardiography test in effort angina pectoris, 452
Dobutamine
Comparative vasoactive therapy for heart failure, 19B
Dopamine
Comparative vasoactive therapy for heart failure, 19B
Doppler ultrasound
See also Echocardiography
Auscultation, M-mode echocardiography and pulsed Doppler echocardiography compared with angiography for diagnosis of chronic aortic regurgitation, 811
Cardiac imaging with ultrasound: rightside up or upside down? 479
Clinical and echocardiographic observations in pulmonary valve endocarditis, 610
Computerized tomography and ultrasound in the noninvasive evaluation of coarctation of the aorta, 822
Detection of intracardiac shunt flow in atrial septal defect using a real-time two-dimensional color-coded Doppler flow imaging system and comparison with contrast two-dimensional echocardiography, 347
Doppler diagnosis of valvular aortic stenosis in patients over 60 years of age, 106
Doppler evaluation of left ventricular diastolic filling in children with systemic hypertension, 921
Doppler hemodynamic evaluation of prosthetic (Starr-Edwards and Björk-Shiley) and bioprosthetic (Hancock and Carpentier-Edwards) cardiac valves, 325
Doppler versus contrast echocardiography for diagnosis of tricuspid regurgitation, 333
Echocardiographic and Doppler flow observations in obstructed and nonobstructed hypertrophic cardiomyopathy, 614
Evaluation of aortic dissection by Doppler color flow mapping, 497
In vitro study of the pressure-velocity relation across stenotic orifices, 465
Quantitative assessment by Doppler echocardiography of pulmonary or aortic regurgitation, 131
Results of balloon valvuloplasty in the treatment of congenital valvar pulmonary stenosis in children, 527
Simplified Doppler estimation of mitral valve area, 488
Subcostal window: a new portal for recording continuous-wave Doppler aortic flow velocities, 199
Usefulness of Doppler echocardiography for determining hemodynamic improvement with intravenous verapamil in hypertrophic cardiomyopathy, 201
Validation of instantaneous pressure gradients measured by continuous-wave Doppler in experimentally induced aortic stenosis, 989
Doxorubicin
Usefulness of a free radical scavenger in preventing doxorubicin-induced heart failure in dogs, 157
Drug addiction
Mitral valve prolapse and addictions, 808

Dysplasia
Arrhythmogenic right ventricular dysplasia in a family, 799

Ebstein's anomaly
Cardiorespiratory response to exercise in Ebstein's anomaly, 509
Echocardiography
See also M-mode echocardiography, two-dimensional echocardiography, Doppler ultrasound
Atrial septal aneurysm: echopolycardiographic study, 653
Clinical and echocardiographic observations in pulmonary valve endocarditis, 610
Doppler versus contrast echocardiography for diagnosis of tricuspid regurgitation, 333
Early cardiac changes related to radiation therapy, 943
Echocardiographic aortic to mitral valve opening area ratio for determining the presence and severity of mitral regurgitation, 115

Transient Q waves during exercise in hypertrophic cardiomyopathy, 491

Exercise testing

Effect of intense aerobic training on exercise performance in children after surgical repair of tetralogy of Fallot or complete transposition of the great arteries, 816

Effects of coenzyme Q_{10} on exercise tolerance in chronic stable angina pectoris, 247

Efficacy of calcium channel blocker therapy for angina pectoris resulting from small-vessel coronary artery disease and abnormal vasodilator reserve, 242

Influence of R-wave amplitude on exercise-induced ST depression: need for a "gain factor" correction when interpreting stress electrocardiograms, 13

Prediction of functional capacity and use of exercise testing for predicting risk after acute myocardial infarction, 839

Relation between heart rate and QT interval in exercise-induced myocardial ischemia, 861

Routine preoperative exercise testing in patients undergoing major noncardiac surgery, 51

Value and limitations of exercise radionuclide angiography for detecting myocardial ischemia in healed myocardial infarction, 1

Value of programmed stimulation and exercise testing in predicting one-year mortality after acute myocardial infarction, 213

Extravascular lung water
Extravascular lung water in children immediately after operative closure of either isolated atrial septal defect or ventricular septal defect, 536

Family history
Coarctation of the aorta inherited as an autosomal dominant trait, 818
Fatty acids
Serum fatty acids, apolipoproteins, selenium and vitamin antioxidants and the risk of death from coronary artery disease, 226
Fiberoptics
Reduction of laser-induced pathologic tissue injury using pulsed energy delivery, 662
Fick technique
Analysis of factors affecting the variability of Fick versus indicator dilution measurements of cardiac output, 764
Measurement of cardiac output during exercise by the thermodilution and direct fick techniques in patients with chronic congestive heart failure, 321
Fontan procedure
Response to the Valsalva maneuver after the Fontan procedure for tricuspid valve atresia, single ventricle or pulmonic valve atresia, 905
From the Editor
Country of origin of articles in the AJC in 1984, 380
How long do physicians live? 838
Mitral valve prolapse and systemic hypertension, 703

Hypertrophic cardiomyopathy
Echocardiographic and Doppler flow observations in obstructed and nonobstructed hypertrophic cardiomyopathy, 614
Left atrial mobile thrombus in hypertrophic cardiomyopathy, 812
Transient Q waves during exercise in hypertrophic cardiomyopathy, 491

Usefulness of Doppler echocardiography for determining hemodynamic improvement with intravenous verapamil in hypertrophic cardiomyopathy, 201

Hypertrophy
Echocardiographic assessment by computer-assisted analysis of diastolic left ventricular function and hypertrophy in borderline or mild systemic hypertension, 546
Effect of diltiazem and ibuprofen on right ventricular hypertrophy in an experimental model of hypoxic pulmonary hypertension, 470

Hypokalemia
Hypokalemia from beta$_2$-receptor stimulation by circulating epinephrine, 3D
Prevention of epinephrine-induced hypokalemia by nonselective beta blockers, 10D

Ibuprofen
Effect of diltiazem and ibuprofen on right ventricular hypertrophy in an experimental model of hypoxic pulmonary hypertension, 470

Infants
Balloon occlusion angiography in infancy: methods, uses and limitations, 495
Diagnosis of cardiac tumors in infants by magnetic resonance imaging, 831
Infusion of blood from pericardial sac into femoral vein: a technique for survival until operative closure of a cardiac perforation during balloon septostomy, 494

Infections
Infections in a coronary care unit, 757

Inotropic drugs
Anion-channel blockade with alinidine: a specific bradycardiac drug for coronary heart disease without negative inotropic activity? 270

Internal mammary artery
Additional evidence for relative resistance to atherosclerosis of the internal mammary artery compared to saphenous vein when used to increase myocardial blood supply, 488
Coronary bypass using the internal mammary artery, 480

Intraaortic balloon pumping
Interhospital transport of patients with ongoing intraaortic balloon pumping, 59

Ischemia
Different susceptibility to myocardial ischemia provoked by hyperventilation and cold pressor test in exertional and variant angina pectoris, 18
Dipyridamole-echocardiography test in effort angina pectoris, 452
Effect of intracoronary thrombolytic therapy on exercise-induced ischemia after acute myocardial infarction, 705
Effects of repeated brief coronary occlusion on regional left ventricular function and dimension in dogs, 473
Efficacy of carvedilol (BM14,190), a new beta-blocking drug with vasodilating properties, in exercise-induced ischemia, 35
Ischemia during angioplasty after streptokinase: a marker of myocardial salvage, 749
Reciprocal electrocardiographic changes in acute myocardial infarction, 23
Relation between electrocardiographic and scintigraphic location of myocardial ischemia in 1-vessel coronary artery disease, 704
Relation between heart rate and QT interval in exercise-induced myocardial ischemia, 861
Silent myocardial ischemia as a manifestation of asymptomatic coronary artery disease: what is appropriate therapy? 28D
Transient ischemia in angina pectoris: frequent silent events with everyday activities, 34E
Value and limitations of exercise radionuclide angiography for detecting myocardial ischemia in healed myocardial infarction, 1

Isoproterenol
Autonomic dependence of ventriculoatrial conduction, 285
Beta-adrenergic stimulation reverses postischemic myocardial dysfunction without producing subsequent functional deterioration, 964

Isosorbide dinitrate
Comparison of buccal nitroglycerin and oral isosorbide dinitrate for nitrate tolerance in stable angina pectoris, 724
Coronary artery dilation and hemodynamic responses after isosorbide dinitrate therapy in patients with coronary artery disease, 390

Jenkins Activity Survey
Type A score (Jenkins Activity Survey) and risk of recurrent coronary heart disease in the aspirin myocardial infarction study, 221

Kawasaki disease
Repeated quantitative angiograms in coronary arterial aneurysm in Kawasaki disease, 846

Krypton-81m
Continuous determination of regional myocardial blood flow with intracoronary krypton-81m in coronary artery disease, 445
Right ventricular ejection fraction measured by first-pass intravenous krypton-81m: reproducibility and comparison with technetium-99m, 776

Labetalol
Double-blind trial comparing labetalol with atenolol in the treatment of systemic hypertension with angina pectoris, 551

Lasers
Effects of hematoporphyrin derivative and photodynamic therapy on atherosclerotic rabbits, 667
Limitations, risks and complications of laser recanalization: a cautious approach warranted, 181
Reduction of laser-induced pathologic tissue injury using pulsed energy delivery, 662
The healing process in normal canine arteries and in atherosclerotic monkey arteries after transluminal laser irradiation, 983

Left atrial mass
Left ventricular apical masses: noninvasive differentiation of rare from common ones, 697
Pericardial defect mimicking a left atrial mass, 699

Left ventricular anatomy
Importance of imaging plane for magnetic resonance imaging of the normal left ventricle, 366

Left ventricular dimension
Left ventricular stress-dimension-shortening relations before and after correction of chronic aortic and mitral regurgitation, 99

Left ventricular function
Acute effects of intravenous nisoldipine on left ventricular function and coronary hemodynamics, 140
Acute left ventricular dysfunction and thrombosis following natural gas poisoning, 814
Arrhythmias and left ventricular function in chronic alcoholics with alcoholic cirrhosis, 825
Coronary sinus occlusion pressure and its relation to intracardiac pressure, 457
Early positive technetium-99m stannous pyrophosphate images as a marker of reperfusion after thrombolytic therapy for acute myocardial infarction, 252
Echocardiographic assessment by computer-assisted analysis of diastolic left ventricular function and hypertrophy in borderline or mild systemic hypertension, 546
Effects of repeated brief coronary occlusion on regional left ventricular function and dimension in dogs, 473
Evaluation of methods of measurement and estimation of left ventricular function after acute myocardial infarction, 753
Influence of the two-stage anatomic correction of simple transposition of the great arteries on left ventricular function, 514
Intravenous amrinone in left ventricular failure complicated by acute myocardial infarction, 29B
Left ventricular thrombi in association with normal left ventricular wall motion in patients with malignancy, 827
Prognostic significance of exercise-induced left ventricular dysfunction in chronic aortic regurgitation, 605
Reproducibility of left ventricular area and volume measurements using a computer endocardial edge-detection algorithm in normal subjects, 947
Ventricular performance in human hearts aged 61 to 73 years, 932
Ventricular remodeling in myocardial infarction—the rat and the human (LE), 910

Left ventricular mass
Determination of left ventricular mass using single-photon emission computed tomography, 761

Left ventricular volume
Left ventricular stress-dimension-shortening relations before and after correction of chronic aortic and mitral regurgitation, 99
Measurement of left ventricular volume using single-photon emission computed tomography, 781
Usefulness of left ventricular volume in assessing tetralogy of Fallot for total correction, 356
Value and limitations of exercise radionuclide angiography for detecting myocardial ischemia in healed myocardial infarction, 1

Letters to the Editor
Assessment of amrinone, 1005
Balloon dilatation catheter size selection, 911
Bucindolol, 704
Cold-induced immersion injury, 1007
Coronary angioplasty in myocardial infarction, 1004

Coronary artery occlusion seven weeks after angioplasty successfully managed with repeat emergency angioplasty, 1007
Evaluation of coronary collateral circulation, 1006
Frequency of pericardial effusion by M-mode echocardiography after acute myocardial infarction, 1006
Ice-water washcloth rather than facial immersion (diving reflex) for supraventricular tachycardia in adults, 1003
Multiple Risk Factor Intervention Trial, 1005
Postextrasystolic potentiation during acute myocardial infarction: predicting presence of viable myocardium, 1003
Relation between electrocardiographic and scintigraphic location of myocardial ischemia in 1-vessel coronary artery disease, 704
Serial electrophysiologic testing after acute myocardial infarction, 704
Subcritical coronary stenosis, 1007

Systolic time intervals in coronary heart disease at rest and during exercise, 910
The origin of giant U waves, 1003
Ventricular remodeling in myocardial infarction—the rat and the human, 910

Magnetic resonance imaging
Diagnosis of cardiac tumors in infants by magnetic resonance imaging, 831
Importance of imaging plane for magnetic resonance imaging of the normal left ventricle, 366
Magnetic resonance imaging in pulmonary arterial hypertension, 938

Mapping
Digital coronary roadmapping as an aid for performing coronary angioplasty, 237
Evaluation of aortic dissection by Doppler color flow mapping, 497
Identification of best electrocardiographic leads for diagnosing myocardial infarction by statistical analysis of body surface potential maps, 852
Simultaneous computer mapping to facilitate intraoperative localization of accessory pathways in patients with Wolff-Parkinson-White syndrome, 571

Methemoglobin
Effects of continuous infusion of intravenous nitroglycerin on methemoglobin levels, 461

Mexiletine
Efficacy of combination therapy with mexiletine and a type IA agent for inducible ventricular tachyarrhythmias secondary to coronary artery disease, 277

Microbubbles
Value of intraoperative left ventricular microbubbles detected by transesophageal two-dimensional echocardiography in predicting neurologic outcome after cardiac operations, 773

Milrinone
Immediate effects of milrinone on metabolic and sympathetic responses to exercise in severe congestive heart failure, 93
Pharmacokinetics and pharmacodynamics of milrinone in chronic congestive heart failure, 685

Mitral regurgitation
Acute hemodynamic effects of nitroprusside in children with isolated mitral regurgitation, 351
Echocardiographic and Doppler flow observations in obstructed and nonobstructed hypertrophic cardiomyopathy, 614
Echocardiographic aortic to mitral valve opening area ratio for determining the presence and severity of mitral regurgitation, 115
Left ventricular stress-dimension-shortening relations before and after correction of chronic aortic and mitral regurgitation, 99

Mitral stenosis
Conduit bypass of mitral valve: a palliative approach to congenital mitral stenosis, 493
Effects of atenolol on exercise capacity in patients with mitral stenosis with sinus rhythm, 598

Mitral valve
Conduit bypass of mitral valve: a palliative approach to congenital mitral stenosis, 493
Doppler hemodynamic evaluation of prosthetic (Starr-Edwards and Björk-Shiley) and bioprosthetic (Hancock and Carpentier-Edwards) cardiac valves, 325
Echocardiographic aortic to mitral valve opening area ratio for determining the presence and severity of mitral regurgitation, 115
Simplified Doppler estimation of mitral valve area, 488

Mitral valve prolapse
Electrophysiologic mechanisms of provoked atrial flutter in mitral valve prolapse syndrome, 602
Mitral valve prolapse and addictions, 808
Mitral valve prolapse, Wolff-Parkinson-White syndrome, His bundle sclerosis and sudden death, 700
Safety of labor and delivery in women with mitral valve prolapse, 806
Upright paradoxical posterior wall movement in mitral valve prolapse, 804

M-mode echocardiography
Auscultation, M-mode echocardiography and pulsed Doppler echocardiography compared with angiography for diagnosis of chronic aortic regurgitation, 811
Doppler evaluation of left ventricular diastolic filling in children with systemic hypertension, 921
Echocardiographic assessment by computer-assisted analysis of diastolic left ventricular function and hypertrophy in borderline or mild systemic hypertension, 546
Frequency of pericardial effusion by M-mode echocardiography after acute myocardial infarction (LE), 1006
Significance of E point–septal separation by M-mode echocardiography in patients with aortic regurgitation, 809

Mortality
Value of programmed stimulation and exercise testing in predicting one-year mortality after acute myocardial infarction, 213

Muscular dystrophy, Becker's
Right-axis deviation and anterior wall thallium-201 defect in Becker's muscular dystrophy, 203

Myocardial enzymes
Hemodynamic and electrocardiographic effects of fructose-1,6-diphosphate in acute myocardial infarction, 266
Time course of alpha-1-acid glycoprotein and its relation to myocardial enzymes after acute myocardial infarction, 262

Myocardial infarction
Are the findings from the randomized Coronary Artery Surgery Study (CASS) of value in the management of patients soon after acute myocardial infarction? 179
Atrial fibrillation in acute myocardial infarction, 27
Collateral flow in patients with acute myocardial infarction, 729
Complete pulmonic valve opening during atrial contraction after right ventricular infarction, 486
Coronary angioplasty in myocardial infarction (LE), 1004
Coronary artery aneurysm producing right ventricular outflow obstruction, 192
Differentiation between acute and healed myocardial infarction by signal averaging and color encoding two-dimensional echocardiography, 381
Early positive technetium-99m stannous pyrophosphate images as a marker of reperfusion after thrombolytic therapy for acute myocardial infarction, 252
Echocardiographic detection of complete and partial papillary muscle rupture during acute myocardial infarction, 787
Effect of intracoronary thrombolytic therapy on exercise-induced ischemia after acute myocardial infarction, 705
Effect of intracoronary verapamil on infarct size in the ischemic, reperfused canine heart: critical importance of the timing of treatment, 672
Effect of ventricular fibrillation complicating acute myocardial infarction on long-term prognosis: importance of the site of infarction, 384
Evaluation of methods of measurement and estimation of left ventricular function after acute myocardial infarction, 753
Frequency and significance of induced sustained ventricular tachycardia or fibrillation two weeks after acute myocardial infarction, 737
Frequency of pericardial effusion by M-mode echocardiography after acute myocardial infarction (LE), 1006
Hemodynamic and electrocardiographic effects of fructose-1,6-diphosphate in acute myocardial infarction, 266
Identification of best electrocardiographic leads for diagnosing myocardial infarction by statistical analysis of body surface potential maps, 852
Intravenous amrinone in left ventricular failure complicated by acute myocardial infarction, 29B
Left ventricular thrombi diagnosed by echocardiography in patients with acute myocardial infarction treated with intracoronary streptokinase followed by intravenous heparin, 422
Malignant arrhythmia in relation to serum potassium in acute myocardial infarction, 20D
Post–cardiac injury syndrome and an increased humoral immune response against the major contractile proteins (actin and myosin), 631
Postextrasystolic potentiation during acute myocardial infarction: predicting presence of viable myocardium (LE), 1003
Prediction of functional capacity and use of exercise testing for predicting risk after acute myocardial infarction, 839
Reciprocal electrocardiographic changes in acute myocardial infarction, 23

Regional left ventricular wall motion assessment: comparison of two-dimensional echocardiography and radionuclide angiography with contrast angiography in healed myocardial infarction, 8
Relation of acute myocardial infarction to cocaine abuse, 794
Relation of effectiveness of intracoronary thrombolysis in acute myocardial infarction to systemic thrombolytic state, 441
Relation of myocardial salvage to size of myocardium at risk in dogs, 974
Serial electrophysiologic testing after acute myocardial infarction, 704
Sudden death and experimental acute myocardial infarction, 677
Summary III: implications for therapy after myocardial infarction, 55D
Time course of alpha-1-acid glycoprotein and its relation to myocardial enzymes after acute myocardial infarction, 262
Type A score (Jenkins Activity Survey) and risk of recurrent coronary heart disease in the aspirin myocardial infarction study, 221
Unrecognized Q-wave myocardial infarction in patients older than 64 years in a long-term health-care facility, 483
Value and limitations of exercise radionuclide angiography for detecting myocardial ischemia in healed myocardial infarction, 1
Value of programmed stimulation and exercise testing in predicting one-year mortality after acute myocardial infarction, 213

Myocardial perfusion
Usefulness of defibrotide in protecting ischemic myocardium from early reperfusion damage, 978

Myocarditis
Early cardiac changes related to radiation therapy, 943

Myocardium
Myocardial kinetics of thallium-201 after stress in normal and perfusion-reduced canine myocardium, 969
Postextrasystolic potentiation during acute myocardial infarction: predicting presence of viable myocardium (LE), 1003
Relation of myocardial salvage to size of myocardium at risk in dogs, 974

Myosin
Post–cardiac injury syndrome and an increased humoral immune response against the major contractile proteins (actin and myosin), 631

N-Acetylcysteine
Usefulness of a free radical scavenger in preventing doxorubicin-induced heart failure in dogs, 157

N-Acetylprocainamide
Electrophysiologic evaluation of the antiarrhythmic effects of N-acetylprocainamide for ventricular tachycardia secondary to coronary artery disease, 877

Nd-YAG laser
Nd-YAG laser fusion of human atheromatous plaque-arterial wall separations in vitro, 953

Nicardipine
Nicardipine for angina pectoris at rest and coronary arterial spasm, 232

Nifedipine
Spectrum of acute hemodynamic effects of nifedipine in severe congestive heart failure, 560

Nisoldipine
Acute effects of intravenous nisoldipine on left ventricular function and coronary hemodynamics, 140

Nitrates
Comparison of buccal nitroglycerin and oral isosorbide dinitrate for nitrate tolerance in stable angina pectoris, 724
Nitrates for congestive heart failure, 19A
Pharmacology of nitroglycerin and long-acting nitrates, 12A

Nitroglycerin
Comparison of buccal nitroglycerin and oral isosorbide dinitrate for nitrate tolerance in stable angina pectoris, 724
Coronary vasomotion in angina at rest and effect of sublingual nitroglycerin on coronary blood flow, 484
Crossover from intravenous to transdermal nitroglycerin therapy in unstable angina pectoris, 742
Effects of continuous infusion of intravenous nitroglycerin on methemoglobin levels, 461
Hemodynamic and hormonal effects of high-dose transdermal nitroglycerin in patients with chronic congestive heart failure, 555
Pharmacology of nitroglycerin and long-acting nitrates, 12A

Nitroprusside
Acute hemodynamic effects of nitroprusside in children with isolated mitral regurgitation, 351

Nitrous oxide entrapment
Pacemaker malfunction after nitrous oxide anesthesia, 995

Norepinephrine
Acute effects of digoxin on total systemic vascular resistance in congestive heart failure due to dilated cardiomyopathy: a hemodynamic-hormonal study, 896
Effect of a benzodiazepine (alprazolam) on plasma epinephrine and norepinephrine levels during exercise stress, 136
Norepinephrine infusions in congestive heart failure, 802
Sympathetic tone in congestive heart failure (LE), 912

Nuclear medicine
Continuous determination of regional myocardial blood flow with intracoronary krypton-81m in coronary artery disease, 445

Orthostatic intolerance
Cardiovascular deconditioning produced by 20 hours of bedrest with head-down tilt (−5°) in middle-aged healthy men, 634

Oxygen
Anion-channel blockade with alinidine: a specific bradycardiac drug for coronary heart disease without negative inotropic activity? 270
Cardiorespiratory response to exercise in Ebstein's anomaly, 509
Effects of amrinone on myocardial energetics in severe congestive heart failure, 16B
Measurement of cardiac output during exercise by the thermodilution and direct fick techniques in patients with chronic congestive heart failure, 321
Pathophysiology of cardiac failure, 3B

Pacemakers
Nonsurgical treatment of the superior vena cava syndrome, 829
Pacemaker malfunction after nitrous oxide anesthesia, 995
Pacemaker Twiddler's syndrome: an important cause of diaphragmatic pacing, 797

Pacing
Continuous determination of regional myocardial blood flow with intracoronary krypton-81m in coronary artery disease, 445
Determination of the optimal timing for performing digital ventriculography during atrial pacing stress tests in coronary heart disease, 426
Effect of basic pacing cycle length on sinus node refractoriness in the rabbit, 162
Entrainment of ventricular tachycardia by atrial depolarizations, 298
Pacemaker Twiddler's syndrome: an important cause of diaphragmatic pacing, 797
Reciprocal electrocardiographic changes in acute myocardial infarction, 23

Papillary muscle rupture
Echocardiographic detection of complete and partial papillary muscle rupture during acute myocardial infarction, 787

Paracentesis
Circulatory shock due to ascites and responsive to paracentesis, 500

Percardial effusion
Frequency of pericardial effusion by M-mode echocardiography after acute myocardial infarction (LE), 1006

Pericardiocentesis
Primary acute pericardial disease: a prospective series of 231 consecutive patients, 623

Pericarditis
Aspergillus Fumigatus thrombi causing total occlusion of both coronary arterial ostia, all four major epicardial coronary arteries and coronary sinus and associated with purulent pericarditis, 499
Early cardiac changes related to radiation therapy, 943
Primary acute pericardial disease: a prospective series of 231 consecutive patients, 623

Pericardium
Pericardial defect mimicking a left atrial mass, 699

Pharmacodynamics
Clinical pharmacology, pharmacodynamics and interactions with esmolol, 14F
Pharmacokinetics and pharmacodynamics of milrinone in chronic congestive heart failure, 685

Pharmacokinetics
Cardiovascular and pharmacokinetic consequences of combined administration of verapamil and propranolol in dogs, 147
Circulatory effects of coffee in relation to the pharmacokinetics of caffeine, 958
Pharmacokinetics and pharmacodynamics of milrinone in chronic congestive heart failure, 685
Pharmacology of nitroglycerin and long-acting nitrates, 12A

Pharmacology
Pharmacology of nitroglycerin and long-acting nitrates, 12A

Phonocardiography
Phonocardiographic characteristics of the total artificial heart, 205

Platelets
Usefulness of defibrotide in protecting ischemic myocardium from early reperfusion damage, 978
Plexectomy
Surgical treatment of medically refractory variant angina pectoris: segmental coronary resection with aortocoronary bypass and plexectomy, 792
Post-cardiac injury syndrome
Post-cardiac injury syndrome and an increased humoral immune response against the major contractile proteins (actin and myosin), 631
Potassium
Effects of exercise on blood pressure, plasma catecholamines, potassium and the electrocardiogram after diuretic and neural-blocking therapy for moderate hypertension, 39D
Malignant arrhythmia in relation to serum potassium in acute myocardial infarction, 20D
Pregnancy
Amiodarone in pregnancy, 196
Safety of labor and delivery in women with mitral valve prolapse, 806
Procainamide
Combination of procainamide and quinidine for better tolerance and additive effects for ventricular arrhythmias, 84
Efficacy of combination therapy with mexiletine and a type IA agent for inducible ventricular tachyarrhythmias secondary to coronary artery disease, 277
Electropharmacologic testing in sustained ventricular tachycardia associated with coronary heart disease: value of the response to intravenous procainamide in predicting the response to oral procainamide and oral quinidine treatment, 883
Prognosis
Determinants of prognosis in idiopathic dilated cardiomyopathy as determined by programmed electrical stimulation, 337
Effect of ventricular fibrillation complicating acute myocardial infarction on long-term prognosis: importance of the site of infarction, 384
Prognostic significance of exercise-induced left ventricular dysfunction in chronic aortic regurgitation, 605
Programmed stimulation
Usefulness of programmed stimulation in predicting efficacy of propafenone in long-term antiarrhythmic therapy for paroxysmal supraventricular tachycardia, 593
Propafenone
Usefulness of programmed stimulation in predicting efficacy of propafenone in long-term antiarrhythmic therapy for paroxysmal supraventricular tachycardia, 593
Propranolol
Acute hemodynamic and electrophysiologic effects of propranolol in patients receiving diltiazem, 47
Cardiovascular and pharmacokinetic consequences of combined administration of verapamil and propranolol in dogs, 147
Comparative efficacy and tolerance of esmolol to propranolol for control of supraventricular tachyarrhythmia, 33F
Effects of esmolol on cardiac function: evaluation by noninvasive techniques, 27F
Single and combined therapy for systemic hypertension with propranolol, hydralazine and hydrochlorothiazide: hemodynamic and neuroendocrine mechanisms of action, 315
Prostacyclin
Usefulness of defibrotide in protecting ischemic myocardium from early reperfusion damage, 978
Prostheses
Anticoagulation therapy in children with mechanical prosthetic cardiac valves, 533
Doppler hemodynamic evaluation of prosthetic (Starr-Edwards and Björk-Shiley) and bioprosthetic (Hancock and Carpentier-Edwards) cardiac valves, 325
Pulmonary arteries
Effect of pulmonary artery distention on systemic vascular resistance in newborn lambs, 681
Two-dimensional echocardiographic diagnosis of total anomalous pulmonary venous connection below the diaphragm, 821
Pulmonary edema
Extravascular lung water in children immediately after operative closure of either isolated atrial septal defect or ventricular septal defect, 536
Pulmonary hypertension
Effect of diltiazem and ibuprofen on right ventricular hypertrophy in an experimental model of hypoxic pulmonary hypertension, 470
Magnetic resonance imaging in pulmonary arterial hypertension, 938
Pulmonary stenosis
Rest and exercise hemodynamics in pulmonary stenosis: comparison of children and adults, 360
Results of balloon valvuloplasty in the treatment of congenital valvar pulmonary stenosis in children, 527
Pulmonary valve
Clinical and echocardiographic observations in pulmonary valve endocarditis, 610
Complete pulmonic valve opening during atrial contraction after right ventricular infarction, 486
Response to the Valsalva maneuver after the Fontan procedure for tricuspid valve atresia, single ventricle or pulmonic valve atresia, 905

QRS complex
Electrical alternans in wide complex tachycardias, 305
Entrainment of ventricular tachycardia by atrial depolarizations, 298
QRS scoring
Evaluation of methods of measurement and estimation of left ventricular function after acute myocardial infarction, 753
QT interval
Relation between heart rate and QT interval in exercise-induced myocardial ischemia, 861
Quinidine
Combination of procainamide and quinidine for better tolerance and additive effects for ventricular arrhythmias, 84
Comparative efficacy and safety of oral tocainide and quinidine for benign and potentially lethal ventricular arrhythmias, 581
Efficacy of combination therapy with mexiletine and a type IA agent for inducible ventricular tachyarrhythmias secondary to coronary artery disease, 277
Electropharmacologic testing in sustained ventricular tachycardia associated with coronary heart disease: value of the response to intravenous procainamide in predicting the response to oral procainamide and oral quinidine treatment, 883
Incidence of proarrhythmic effects from quinidine in the outpatient treatment of benign or potentially lethal ventricular arrhythmias, 585
Q wave
Transient Q waves during exercise in hypertrophic cardiomyopathy, 491
Unrecognized Q-wave myocardial infarction in patients older than 64 years in a long-term health-care facility, 483

Radiation injuries
Early cardiac changes related to radiation therapy, 943
Radionuclide imaging
Correlation of the exercise ST/HR slope with anatomic and radionuclide cineangiographic findings in stable angina pectoris, 418
Regional left ventricular wall motion assessment: comparison of two-dimensional echocardiography and radionuclide angiography with contrast angiography in healed myocardial infarction, 8
Value and limitations of exercise radionuclide angiography for detecting myocardial ischemia in healed myocardial infarction, 1
Renin
Acute effects of digoxin on total systemic vascular resistance in congestive heart failure due to dilated cardiomyopathy: a hemodynamic-hormonal study, 896
Renin-angiotensin system
Systemic hypertension after cardiac transplantation: effect of cyclosporine on the renin-angiotensin-aldosterone system, 927
Reperfusion
Early positive technetium-99m stannous pyrophosphate images as a marker of reperfusion after thrombolytic therapy for acute myocardial infarction, 252
Effect of intracoronary thrombolytic therapy on exercise-induced ischemia after acute myocardial infarction, 705
Usefulness of defibrotide in protecting ischemic myocardium from early reperfusion damage, 978
Right ventricular function
Assessment of right ventricular outflow tract in children by two-dimensional echocardiography using a new subcostal view. Angiocardiographic and morphologic correlative study, 539
Coronary artery aneurysm producing right ventricular outflow obstruction, 192
Right ventricular ejection fraction measured by first-pass intravenous krypton-81m: reproducibility and comparison with technetium-99m, 776

Right ventricular pressure
Echocardiographic ventricular shape analysis in congenital heart disease with right ventricular volume or pressure overload, 520
Right ventricular volume
Echocardiographic ventricular shape analysis in congenital heart disease with right ventricular volume or pressure overload, 520
Risk factors
Coronary atherosclerosis and antecedent risk factors: pathologic and epidemiologic study in Hisayama, Japan, 62
Factors associated with progression of coronary artery disease in patients with normal or minimally narrowed coronary arteries, 30
Multiple Risk Factor Intervention Trial (LE), 1005
Prediction of functional capacity and use of exercise testing for predicting risk after acute myocardial infarction, 839
Routine preoperative exercise testing in patients undergoing major noncardiac surgery, 51
R wave
Influence of R-wave amplitude on exercise-induced ST depression: need for a "gain factor" correction when interpreting stress electrocardiograms, 13

Saphenous vein
Additional evidence for relative resistance to atherosclerosis of the internal mammary artery compared to saphenous vein when used to increase myocardial blood supply, 488
Scintigraphy
Comparison of stress digital ventriculography, stress thallium scintigraphy, and digital fluoroscopy in the diagnosis of coronary artery disease in subjects without prior myocardial infarction, 434
Effect of intracoronary thrombolytic therapy on exercise-induced ischemia after acute myocardial infarction, 705
Myocardial kinetics of thallium-201 after stress in normal and perfusion-reduced canine myocardium, 969
Relation between electrocardiographic and scintigraphic location of myocardial ischemia in 1-vessel coronary artery disease, 704
Selenium
Serum fatty acids, apolipoproteins, selenium and vitamin antioxidants and the risk of death from coronary artery disease, 226
Sinus node
Effect of basic pacing cycle length on sinus node refractoriness in the rabbit, 162
Sinus rhythm
Effects of atenolol on exercise capacity in patients with mitral stenosis with sinus rhythm, 598
Stenosis
See also Aortic stenosis
Digital quantification eliminates intraobserver and interobserver variability in the evaluation of coronary artery stenosis, 718
Echocardiographic and Doppler flow observations in obstructed and nonobstructed hypertrophic cardiomyopathy, 614
Hemodynamic principles in the control of coronary blood flow, 4E
Nonsurgical treatment of the superior vena cava syndrome, 829
Response of normal and diseased epicardial coronary arteries to vasoactive drugs: quantitative arteriographic studies, 23E
Subcritical coronary stenosis (LE), 1007
Stent creep
Quantitative anatomic analysis of "stent creep" of explanted Hancock standard porcine bioprostheses used for cardiac valve replacement, 110
ST/HR slope
Correlation of the exercise ST/HR slope with anatomic and radionuclide cineangiographic findings in stable angina pectoris, 418
Streptokinase
Early positive technetium-99m stannous pyrophosphate images as a marker of reperfusion after thrombolytic therapy for acute myocardial infarction, 252
Ischemia during angioplasty after streptokinase: a marker of myocardial salvage, 749
Left ventricular thrombi diagnosed by echocardiography in patients with acute myocardial infarction treated with intracoronary streptokinase followed by intravenous heparin, 422
Nonsurgical treatment of the superior vena cava syndrome, 829
Relation of effectiveness of intracoronary thrombolysis in acute myocardial infarction to systemic thrombolytic state, 441
ST segment
Influence of R-wave amplitude on exercise-induced ST depression: need for a "gain factor" correction when interpreting stress electrocardiograms, 13
Superior vena cava
Nonsurgical treatment of the superior vena cava syndrome, 829
Supraventricular tachycardia
Atrioventricular nodal supraventricular tachycardia, 193
Comparative efficacy and tolerance of esmolol to propranolol for control of supraventricular tachyarrhythmia, 33F
Electrical alternans in wide complex tachycardias, 305
Ice-water washcloth rather than facial immersion (diving reflex) for supraventricular tachycardia in adults (LE), 1003
Usefulness of programmed stimulation in predicting efficacy of propafenone in long-term antiarrhythmic therapy for paroxysmal supraventricular tachycardia, 593
Surgery

QUINTON'S CLEAR-LEAD® IS THE CLEAR CHOICE FOR ECG MONITORING.

Don't let ECG leadwires get in the way of your nuclear and imaging studies. Get the whole picture with Quinton's new CLEAR-LEAD radiotransparent leadwires.

Use them with our line of radiolucent electrodes. Together, they're the clear choice for the cath lab. The nuclear medicine department. The critical care unit. Wherever you need ECG *and* a clear picture.

The quality choice.

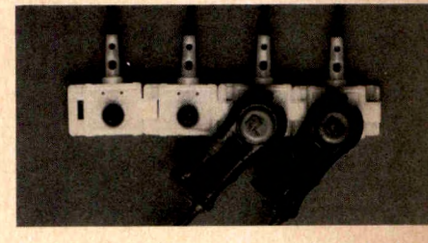
With Quinton's new CLEAR-LEAD technology, the leadwires and electrodes don't interfere with your picture so you can position the electrodes where they'll get the most accurate signal possible.

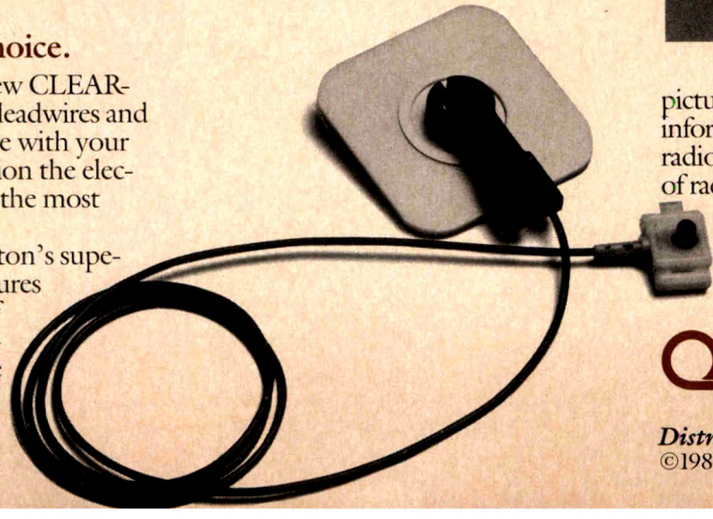
And because Quinton's superior electrode design insures a continuous column of gel, you'll get a dependable signal. With a more stable baseline. And less motion artifact. Even if the patient's moving.

The practical choice.

Unlike other radiotransparent leadwires, Quinton's new CLEAR-LEAD leadwire sets are reusable. You'll get up to 100 uses out of each wire—making them the practical choice when it comes to budgeting.

What's more, CLEAR-LEAD is designed to work with virtually any ECG equipment in use today. Its convenient junction box serves as a link between the machine's own leadwires and the CLEAR-LEAD set.





Isn't it time you got the whole picture? The choice is clear. For more information about CLEAR-LEAD radiotransparent leadwires or our line of radiolucent electrodes, call or write Quinton Instrument Company, 2121 Terry Avenue, Seattle, WA 98121, 1-800-431-1114. Telex 3794094.

The 2kg warning in CHF...

Does it signal a change in the classic Lasix®-digitalis regimen?

BRAND OF
furosemide

For your CHF patients, a 2 kg weight gain might be as innocent as being weighed in winter boots or right after an overindulgent Thanksgiving.

Or, it could mean decompensation.

When the patient has been stabilized on a regimen of Lasix® and digitalis, the possibility of some change in that regimen should be part of your differential diagnosis. Because the diuretic/digitalis/electrolyte balance is so sensitive that even a minor variation could have profound consequences.

Lasix® quality hasn't varied in 20 years and almost 8 billion tablets. So, it's only logical to specify Lasix® by brand name and prevent generic substitution. That's the only way you can be sure your patient will always receive the same brand of furosemide tablets—exactly the same formulation and manufacturing process, with the same excipients and binders—with every single refill.

In fact, 9 out of 10 cardiologists specify Lasix® by brand name, and 2 out of 3 take the extra step to prevent generic substitution.[1] Because in CHF, there's no room for variables.

Specify:

LASIX® 20 mg, 40 mg, 80 mg Tablets

BRAND OF
FUROSEMIDE

One less cause for concern

Please see following page for reference and brief summary of full prescribing information.

©1985 by Hoechst-Roussel Pharmaceuticals Incorporated.

Reference: 1. National survey of 2,960 physicians, including 1,502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey, August 1982.

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.
There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

CORONARY HEART DISEASE

1 **Value and Limitations of Exercise Radionuclide Angiography for Detecting Myocardial Ischemia in Healed Myocardial Infarction.** Gary D. Plotnick, Lewis C. Becker, and Michael L. Fisher

8 **Regional Left Ventricular Wall Motion Assessment: Comparison of Two-Dimensional Echocardiography and Radionuclide Angiography with Contrast Angiography in Healed Myocardial Infarction.** Anthony P. Freeman, Robert W. Giles, Warren F. Walsh, Richard Fisher, I. Provan C. Murray, and David E.L. Wilcken

13 **Influence of R-Wave Amplitude on Exercise-Induced ST Depression: Need for a "Gain Factor" Correction When Interpreting Stress Electrocardiograms.** Milton Hollenberg, Mateo Go, Jr., Barry M. Massie, Judith A. Wisneski, and Edward W. Gertz

18 **Different Susceptibility to Myocardial Ischemia Provoked by Hyperventilation and Cold Pressor Test in Exertional and Variant Angina Pectoris.** Filippo Crea, Graham Davies, Sergio Chierchia, Franco Romeo, Raffaele Bugiardini, Juan Carlos Kaski, Ben Freedman, and Attilio Maseri

23 **Reciprocal Electrocardiographic Changes in Acute Myocardial Infarction.** Dan Tzivoni, Adrian Chenzbraun, Andre Keren, Jesaia Benhorin, Shmuel Gottlieb, Eva Lonn, and Shlomo Stern

27 **Atrial Fibrillation in Acute Myocardial Infarction.** Tetsuro Sugiura, Toshiji Iwasaka, Akio Ogawa, Yoshihachiro Shiroyama, Hisako Tsuji, Hideki Onoyama, and Mitsuo Inada

30 **Factors Associated with Progression of Coronary Artery Disease in Patients with Normal or Minimally Narrowed Coronary Arteries.** Alain Moise, Pierre Théroux, Yves Taeymans, and David D. Waters

35 **Efficacy of Carvedilol (BM14,190), A New Beta-Blocking Drug with Vasodilating Properties, in Exercise-Induced Ischemia.** Jaun Carlos Kaski, Luis Rodriguez-Plaza, John Brown, and Atillio Maseri

41 **Coronary Hemodynamic Responses During Spontaneous Angina in Patients With and Patients Without Coronary Artery Spasm.** Robert G. Macdonald, Robert L. Feldman, James A. Hill, C. Richard Conti, and Carl J. Pepine

47 **Acute Hemodynamic and Electrophysiologic Effects of Propranolol in Patients Receiving Diltiazem.** Christopher L. Wolfe, Gregory D. Tilton, L. David Hillis, Nayer el Ashram, and Michael D. Winniford

51 **Routine Preoperative Exercise Testing in Patients Undergoing Major Noncardiac Surgery.** Nathan H. Carliner, Michael L. Fisher, Gary D. Plotnick, Hadley Garbart, Aaron Rapoport, Michael H. Kelemen, George W. Moran, Thomas Gadacz, and Robert W. Peters

59 **Interhospital Transport of Patients with Ongoing Intraaortic Balloon Pumping.** Joseph LoCicero III, Renee S. Hartz, John H. Sanders, Jr., David C. Hueter, Timothy J. McDonough, and Lawrence L. Michaelis

62 **Coronary Atherosclerosis and Antecedent Risk Factors: Pathologic and Epidemiologic Study in Hisayama, Japan.** Noriya Okumiya, Kenzo Tanaka, Kazuo Ueda, and Teruo Omae

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

67 **Analysis of the Spontaneous Variability of Ventricular Arrhythmias: Consecutive Ambulatory Electrocardiographic Recordings of Ventricular Tachycardia.** Craig M. Pratt, Donald J. Slymen, Ann M. Wierman, James B. Young, Marilyn J. Francis, A. Allen Seals, Miguel A. Quinones, and Robert Roberts

73 **Effects of High Stimulation Current on the Induction of Ventricular Tachycardia.** Fred Morady, Lorenzo A. Dicarlo, Jr., L. Bing Liem, Ryszard B. Krol, and Jeffrey M. Baerman

79 **Nonsustained Ventricular Tachycardia During Programmed Ventricular Stimulation: Criteria for a Positive Test.** Edward V. Platia and Philip R. Reid

84 **Combination of Procainamide and Quinidine for Better Tolerance and Additive Effects for Ventricular Arrhythmias.** Soo G. Kim, Steven W. Seiden, Jeffrey A. Matos, Lawrence E. Waspe, and John D. Fisher

89 **Value of Hepatic Computerized Tomographic Scanning During Amiodarone Therapy.** James Markos, Maurice E. Veronese, Michael R. Nicholson, Stuart McLean, and John E. Shevland

CONGESTIVE HEART FAILURE

93 **Immediate Effects of Milrinone on Metabolic and Sympathetic Responses to Exercise in Severe Congestive Heart Failure.** Harvey D. White, Jorge Pinto Ribeiro, L. Howard Hartley, and Wilson S. Colucci

VALVULAR HEART DISEASE

99 **Left Ventricular Stress-Dimension-Shortening Relations Before and After Correction of Chronic Aortic and Mitral Regurgitation.** Michael R. Zile, William H. Gaasch, and Herbert J. Levine

106 **Doppler Diagnosis of Valvular Aortic Stenosis in Patients Over 60 Years of Age.** Arthur S. Agatston, Mathew Chengot, Aswath Rao, Frank Hildner, and Philip Samet

110 **Quantitative Anatomic Analysis of "Stent Creep" of Explanted Hancock Standard Porcine Bioprostheses Used for Cardiac Valve Replacement.** Frederick J. Schoen, Lois J. Schulman, and Lawrence H. Cohn

115 **Echocardiographic Aortic to Mitral Valve Opening Area Ratio for Determining the Presence and Severity of Mitral Regurgitation.** Thomas Hofmann, Wolfgang Kasper, Thomas Meinertz, and Hanjörg Just

MISCELLANEOUS TOPICS

119 **Effects of Caffeine on Vascular Resistance, Cardiac Output and Myocardial Contractility in Young Men.** Gwendolyn A. Pincomb, William R. Lovallo, Richard B. Passey, Thomas L. Whitsett, Steven M. Silverstein, and Michael F. Wilson

123 **Utility of Two-Dimensional Echocardiography in Suspected Ascending Aortic Dissection.** Jerome E. Granato, Paul Dee, and Robert S. Gibson

METHODS

131 **Quantitative Assessment by Doppler Echocardiography of Pulmonary or Aortic Regurgitation.** Stanley J. Goldberg and Hugh D. Allen

CARDIOVASCULAR PHARMACOLOGY

136 **Effect of Benzodiazepine (Alprazolam) or Plasma Epinephrine and Norepinephrine Levels During Exercise Stress.** John R. Stratton and Jeffrey B. Halter

140 **Acute Effects of Intravenous Nisoldipine on Left Ventricular Function and Coronary Hemodynamics.** Patrick W. Serruys, Haryanto Suryapranata, Juan Planellas, William Wijns, Guido L.J. Vanhaleweyk, Alan Soward, Brian E. Jaski, and Paul G. Hugenholtz

EXPERIMENTAL STUDIES

147 **Cardiovascular and Pharmacokinetic Consequences of Combined Administration of Verapamil and Propranolol in Dogs.** Scott R. Hamann, Kent E. Kaltenborn, Mary Vore, Tiong G. Tan, and R.G. McAllister, Jr.

157 **Usefulness of a Free Radical Scavenger in Preventing Doxorubicin-Induced Heart Failure in Dogs.** Donald V. Unverferth, Carl V. Leier, Stanley P. Balcerzak, and Robert L. Hamlin

162 **Effect of Basic Pacing Cycle Length on Sinus Node Refractoriness in the Rabbit.** Charles R. Kerr, Harold C. Strauss, and Nanda Aiama

HISTORICAL STUDIES

169 **Paul Dudley White: To Know Him Better.** J. Willis Hurst

177 **Remembrances of Paul Dudley White.** W. Proctor Harvey

EDITORIALS

179 **Are the Findings from the Randomized Coronary Artery Surgery Study (CASS) of Value in the Management of Patients Soon After Acute Myocardial Infarction?** Shahbudin H. Rahimtoola

181 **Limitations, Risks and Complications of Laser Recanalization: A Cautious Approach Warranted.** Garrett Lee, Richard M. Ikeda, Ming C. Chan, Marshall H. Lee, John L. Rink, Robert L. Reis, Jerold H. Theis, Reginald Low, William J. Bommer, Andrew H. Kung, Elias S. Hanna, and Dean T. Mason

185 **Antiarrhythmic Drug Classification: New Science and Practical Applications.** Donald C. Harrison

187 **Programmed Electrical Stimulation of the Heart in Ventricular Arrhythmias.** Pedro Brugada and Hein J.J. Wellens

BRIEF REPORTS

191 **Ventricular Fibrillation During Coronary Angiography: Association with Potassium-Containing Glyceryl Trinitrate.** Peter J. Quigley and Brian J. Maurer

192 **Coronary Artery Aneurysm Producing Right Ventricular Outflow Obstruction.** Sidney O. Gottlieb, Diane Solomon, James L. Weiss, and Stephen C. Achuff

193 **Atrioventricular Nodal Supraventricular Tachycardia.** Joseph A. Vassallo, Dennis M. Cassidy, and Mark E. Josephson

196 **Amiodarone in Pregnancy.** Ian M. Penn, Peter A. Barrett, Victor Pannikote, Peter F. Barnaby, John B. Campbell, and Norman R. Lyons

197 **Prevalence of Brown Adipose Tissue in Chronic Congestive Heart Failure Secondary to Coronary Heart Disease.** Frank G. Shellock, Mary S. Riedinger, Michael C. Fishbein, and Prediman K. Shah

199 **Subcostal Window: A New Portal for Recording Continuous-Wave Doppler Aortic Flow Velocities.** Martha L. Ramirez, Maylene Wong, and Pravin M. Shah

201 **Usefulness of Doppler Echocardiography for Determining Hemodynamic Improvement with Intravenous Verapamil in Hypertrophic Cardiomyopathy.** Michael Cooper, Robert Shaddy, Norman Silverman, and Marlene Enderlein

203 **Right-Axis Deviation and Anterior Wall Thallium-201 Defect in Becker's Muscular Dystrophy.** Robert N. Levin and Kenneth A. Narahara

204 **Localized Aortic Dissection with Rupture into the Right Atrium: Diagnosis by Computed Tomography and Cardiac Catheterization.** Adam D. Timmis, Michael D. Rosin, and Shenaz Ramtoola

205 **Phonocardiographic Characteristics of the Total Artificial Heart.** Fred L. Anderson

206 **A Simple Device to Obtain Reproducible Echocardiographic Apical Cross Sections.** Cees A. Visser, Gerard Kan, and Arend J. Dunning, *With the technical assistance of* Arie Steenbeek

CONTENTS: VOLUME 56 • NUMBER 8 — SEPTEMBER 15, 1985

CONGENITAL HEART DISEASE

509 **Cardiorespiratory Response to Exercise in Ebstein's Anomaly.** Gerald Barber, Gordon K. Danielson, Charles T. Heise, and David J. Driscoll

514 **Influence of the Two-Stage Anatomic Correction of Simple Transposition of the Great Arteries on Left Ventricular Function.** Hans H. Sievers, Peter E. Lange, Dietrich G.W. Onnasch, Rosemary Radley-Smith, Magdi H. Yacoub, Paul H. Heintzen, Dieter Regensburger, and Alexander Bernhard

520 **Echocardiographic Ventricular Shape Analysis in Congenital Heart Disease with Right Ventricular Volume or Pressure Overload.** Annabelle Azancot, Thomas Caudell, Hugh D. Allen, George Toscani, Jean Louis Debrux, Anna Lamberti, David J. Sahn, and Stanley J. Goldberg

527 **Results of Balloon Valvuloplasty in the Treatment of Congenital Valvar Pulmonary Stenosis in Children.** Daniel A. Kveselis, Albert P. Rocchini, A. Rebecca Snider, Amnon Rosenthal, Dennis C. Crowley, and Macdonald Dick II

533 **Anticoagulation Therapy in Children with Mechanical Prosthetic Cardiac Valves.** Linda M. Bradley, Frank M. Midgley, Donald C. Watson, Pamela R. Getson, and Lewis P. Scott

536 **Extravascular Lung Water in Children Immediately After Operative Closure of Either Isolated Atrial Septal Defect or Ventricular Septal Defect.** Robert N. Vincent, Peter Lang, E. Marsha Elixson, Richard Jonas, and Aldo R. Castaneda

539 **Assessment of Right Ventricular Outflow Tract in Children by Two-Dimensional Echocardiography Using a New Subcostal View: Angiocardiographic and Morphologic Correlative Study.** Karl Isaaz, Jean L. Cloez, Nicolas Danchin, François Marçon, Anne M. Worms, and Claude Pernot

SYSTEMIC HYPERTENSION

546 **Echocardiographic Assessment by Computer-Assisted Analysis of Diastolic Left Ventricular Function and Hypertrophy in Borderline or Mild Systemic Hypertension.** Vasilios Papademetriou, John S. Gottdiener, Ross D. Fletcher, and Edward D. Freis

551 **Double-Blind Trial Comparing Labetalol with Atenolol in the Treatment of Systemic Hypertension with Angina Pectoris.** Larry D. Jee and Lionel H. Opie

CONGESTIVE HEART FAILURE

555 **Hemodynamic and Hormonal Effects of High-Dose Transdermal Nitroglycerin in Patients with Chronic Congestive Heart Failure.** Uri Elkayam, Arie Roth, Boris Henriquez, Laura Weber, David Tonnemacher, and Shahbudin H. Rahimtoola

560 **Spectrum of Acute Hemodynamic Effects of Nifedipine in Severe Congestive Heart Failure.** Uri Elkayam, Laura Weber, Charles McKay, and Shahbudin Rahimtoola

566 **Effects of Enalapril on Ventricular Arrhythmias in Congestive Heart Failure.** Mark W.I. Webster, M. Andrew Fitzpatrick, M. Gary Nicholls, Hamid Ikram, and J. Elisabeth Wells

Instructions to Authors on page 570

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

571 **Simultaneous Computer Mapping to Facilitate Intraoperative Localization of Accessory Pathways in Patients with Wolff-Parkinson-White Syndrome.** Jeffrey B. Kramer, Peter B. Corr, James L. Cox, Francis X. Witkowski, and Michael E. Cain

577 **Prospective Comparison of Holter Monitoring and Electrophysiologic Study in Patients with Coronary Artery Disease and Sustained Ventricular Tachyarrhythmias.** Charles D. Swerdlow and Jan Peterson

581 **Comparative Efficacy and Safety of Oral Tocainide and Quinidine for Benign and Potentially Lethal Ventricular Arrhythmias.** Joel Morganroth, Carl Oshrain, and Peter P. Steele

585 **Incidence of Proarrhythmic Effects from Quinidine in the Outpatient Treatment of Benign or Potentially Lethal Ventricular Arrhythmias.** Joel Morganroth and Leonard N. Horowitz

588 **Ambulatory Electrocardiographic Recordings at the Time of Fatal Cardiac Arrest.** Peter G. Milner, Edward V. Platia, Philip R. Reid, and Lawrence S.C. Griffith

593 **Usefulness of Programmed Stimulation in Predicting Efficacy of Propafenone in Long-Term Antiarrhythmic Therapy for Paroxysmal Supraventricular Tachycardia.** Matthias Manz, Gerhard Steinbeck, and Berndt Lüderitz

VALVULAR HEART DISEASE

598 **Effects of Atenolol on Exercise Capacity in Patients with Mitral Stenosis with Sinus Rhythm.** Herman O. Klein, Pinhas Sareli, Colon L. Schamroth, Yoonoos Carim, Menashe Epstein, and Bridget Marcus

602 **Electrophysiologic Mechanisms of Provoked Atrial Flutter in Mitral Valve Prolapse Syndrome.** David J. Dobmeyer, Ronald A. Stine, Carl V. Leier, and Stephen F. Schaal

605 **Prognostic Significance of Exercise-Induced Left Ventricular Dysfunction in Chronic Aortic Regurgitation.** David S. Gee, Jack E. Juni, John T. Santinga, and Andrew J. Buda

610 **Clinical and Echocardiographic Observations in Pulmonary Valve Endocarditis.** Anne-Claude Cremieux, Serge Witchitz, Marie-Christine Malergue, Michel Wolff, Daniel Vittecocq, Jean-Louis Vilde, Jacques Frottier, Pierre Etienne Valere, Claude Gibert, and Adrien G. Saimot

CARDIOMYOPATHY

614 **Echocardiographic and Doppler Flow Observations in Obstructed and Nonobstructed Hypertrophic Cardiomyopathy.** Julius M. Gardin, Ali Dabestani, Gordon A. Glasgow, Samuel Butman, Cora S. Burn, and Walter L. Henry

MISCELLANEOUS TOPICS

623 **Primary Acute Pericardial Disease: A Prospective Series of 231 Consecutive Patients.** G. Permanyer-Miralda, J. Sagristá-Sauleda, and J. Soler-Soler

631 **Post-Cardiac Injury Syndrome and an Increased Humoral Immune Response Against the Major Contractile Proteins (Actin and Myosin).** Ivan de Scheerder, Joel Vandekerckhove, Johan Robbrecht, Luc Algoed, Marc de Buyzere, Joris de Langhe, Guido de Schrijver, and Denis Clement

634 **Cardiovascular Deconditioning Produced by 20 Hours of Bedrest with Head-Down Tilt (−5°) in Middle-Aged Healthy Men.** F. Andrew Gaffney, J.V. Nixon, Erlin S. Karlsson, William Campbell, A.B.C. Dowdey, and C. Gunnar Blomqvist

639 **Safety of Outpatient Cardiac Catheterizations.** W. Peter Klinke, George Kubac, Tal Talibi, and Simon J.K. Lee

642 **Relation of Hemoglobin A_1 and Blood Glucose to Cardiac Function in Diabetes Mellitus.** Richard S. Goldweit, Jeffrey S. Borer, Lois G. Jovanovic, Andrew J. Drexler, Clare A. Hochreiter, Richard B. Devereux, and Charles M. Peterson

647 **Electrophysiologic Evaluation of the Cardiac Conduction System and Its Autonomic Regulation in Familial Amyloid Polyneuropathy.** Bo Lennart Bergfeldt, Bert-Ove Olofsson, and Knut Olof Edhag

653 **Atrial Septal Aneurysm: Echopolycardiographic Study.** Carlo Longhini, Maria Christiana Brunazzi, Gianfranca Musacci, Marzia Caneva, Attilio Bandello, Lorenzo Bolomini, Mario Barbiero, Tiziano Toselli, and Franco Barbaresi

EXPERIMENTAL STUDIES

657 **Measurement of Cardiac Output by Cine Computed Tomography.** Jeffrey S. Garrett, Peter Lanzer, Werner Jaschke, Elias Botvinick, Richard Sievers, Charles B. Higgins, and Martin J. Lipton

662 **Reduction of Laser-Induced Pathologic Tissue Injury Using Pulsed Energy Delivery.** Lawrence I. Deckelbaum, Jeffrey M. Isner, Roberta Fortin Donaldson, Richard H. Clarke, Sylvie Laliberte, Alon S. Aharon, and Jeffrey S. Bernstein

667 **Effects of Hematoporphyrin Derivative and Photodynamic Therapy on Atherosclerotic Rabbits.** Frank Litvack, Warren S. Grundfest, James S. Forrester, Michael Fishbein, H.J.C. Swan, Eliot Corday, David M. Rider, I. Stewart McDermid, Thomas J. Pacala, and James B. Laudenslager

672 **Effect of Intracoronary Verapamil on Infarct Size in the Ischemic, Reperfused Canine Heart: Critical Importance of the Timing of Treatment.** Huey-Ming Lo, Robert A. Kloner, and Eugene Braunwald

677 **Sudden Death and Experimental Acute Myocardial Infarction.** Yvette Trolese-Mongheal, Pierre Duchene-Marullaz, Jean-Francois Trolese, Michel Leinot, Jean-Claude Lamar, and Pierre Lacroix

681 **Effect of Pulmonary Artery Distention on Systemic Vascular Resistance in Newborn Lambs.** Jay M. Milstein and Boyd W. Goetzman

CONGESTIVE HEART FAILURE

685 **Pharmacokinetics and Pharmacodynamics of Milrinone in Chronic Congestive Heart Failure.** Joseph R. Benotti, Lawrence J. Lesko, Jane E. McCue, and Joseph S. Alpert

690 **Effects of Hydralazine on Pressure-Volume and Stress-Volume Relations in Congestive Heart Failure Secondary to Idiopathic Dilated Cardiomyopathy.** Mark L. Smucker, C. Fagg Sanford, and Kirk M. Lipscomb

BRIEF REPORTS

697 **Left Ventricular Apical Masses: Noninvasive Differentiation of Rare from Common Ones.** Andre Keren, Toshihiko Takamoto, Donald C. Harrison, and Richard L. Popp

699 **Pericardial Defect Mimicking a Left Atrial Mass.** Barry S. Talesnick, Frederick J. Sutton, Yu-Chen Lee, and Joseph S. McLaughlin

700 **Mitral Valve Prolapse, Wolff-Parkinson-White Syndrome, His Bundle Sclerosis and Sudden Death.** Xavier André-Fouët, Ahmiadziah Tabib, Philippe Jean-Louis, Didier Anne, Paul Dutertre, Christian Gayet, Alain Huygue de Mahenge, Robert Loire, and Maurice Pont

CORONARY HEART DISEASE

705 **Effect of Intracoronary Thrombolytic Therapy on Exercise-Induced Ischemia After Acute Myocardial Infarction.** Jacques A. Melin, Patrick M. De Coster, Jean Renkin, Jean-Marie R. Detry, Christian Beckers, and Jacques Col

712 **Primary Angiographic Success Rates of Percutaneous Transluminal Coronary Angioplasty.** H. Vernon Anderson, Gary S. Roubin, Pierre P. Leimgruber, John S. Douglas, Jr., Spencer B. King III, and Andreas R. Gruentzig

718 **Digital Quantification Eliminates Intraobserver and Interobserver Variability in the Evaluation of Coronary Artery Stenosis.** Ran Vas, Neal Eigler, Calvin Miyazono, J. Martin Pfaff, Kenneth J. Resser, Mason Weiss, Thasana Nivatpumin, James Whiting, and James Forrester

724 **Comparison of Buccal Nitroglycerin and Oral Isosorbide Dinitrate for Nitrate Tolerance in Stable Angina Pectoris.** John O. Parker, Karen A. Vankoughnett, and Bernice Farrell

729 **Collateral Flow in Patients with Acute Myocardial Infarction.** William D. Nitzberg, Hrudaya P. Nath, William J. Rogers, William P. Hood, Jr., Patrick L. Whitlow, Russell Reeves, and William A. Baxley

737 **Frequency and Significance of Induced Sustained Ventricular Tachycardia or Fibrillation Two Weeks After Acute Myocardial Infarction.** Anil K. Bhandari, Jeffrey S. Rose, Adam Kotlewski, Shahbudin H. Rahimtoola, and Delon Wu

742 **Crossover from Intravenous to Transdermal Nitroglycerin Therapy in Unstable Angina Pectoris.** Shu-Guang Lin and John T. Flaherty

749 **Ischemia During Angioplasty After Streptokinase: A Marker of Myocardial Salvage.** Lowell F. Satler, Charles E. Rackley, Curtis E. Green, Randolph S. Pallas, David L. Pearle, Albert A. Del Negro, and Kenneth M. Kent

753 **Evaluation of Methods of Measurement and Estimation of Left Ventricular Function After Acute Myocardial Infarction.** Michael G. Jones, Barry W. Ramo, Gilbert L. Raff, Tomoaki Hinohara, and Galen S. Wagner

757 **Infections in a Coronary Care Unit.** Winston A. Schandorf, Richard B. Brown, Michael Sands, and David Hosmer

METHODS

761 **Determination of Left Ventricular Mass Using Single-Photon Emission Computed Tomography.** Christopher L. Wolfe, Donald E. Jansen, James R. Corbett, Kirk Lipscomb, Gregory Gabliani, Neil Filipchuk, Gregory Redish, Samuel E. Lewis, and James T. Willerson

764 **Analysis of Factors Affecting the Variability of Fick Versus Indicator Dilution Measurements of Cardiac Output.** L. David Hillis, Brian G. Firth, and Michael D. Winniford

769 **Effect of Damped Sine-Wave Shocks on Catheter Dielectric Strength.** Gust H. Bardy, Fernando Coltorti, Tom D. Ivey, Dan Yerkovich, and H. Leon Greene

773 **Value of Intraoperative Left Ventricular Microbubbles Detected by Transesophageal Two-Dimensional Echocardiography in Predicting Neurologic Outcome After Cardiac Operations.** Eric J. Topol, Linda S. Humphrey, A. Michael Borkon, William A. Baumgartner, Debra L. Dorsey, Bruce A. Reitz, and James L. Weiss

776 **Right Ventricular Ejection Fraction Measured by First-Pass Intravenous Krypton-81m: Reproducibility and Comparison with Technetium-99m.** Dean F. Wong, T.K. Natarajan, Warren Summer, Paul A. Tibbits, Thomas Beck, Daniel Koller, Wayne Kasecamp, James Lamb, Joseph Olynyk, Mary Sue Philp, Marshall Bryan, and Henry N. Wagner, Jr.

781 **Measurement of Left Ventricular Volume Using Single-Photon Emission Computed Tomography.** Gary R. Caputo, Michael M. Graham, Kirk D. Brust, J. Ward Kennedy, and Wil B. Nelp

BRIEF REPORTS

787 **Echocardiographic Detection of Complete and Partial Papillary Muscle Rupture During Acute Myocardial Infarction.** Patricia C. Come, Marilyn F. Riley, Ronald Weintraub, James P. Morgan, and Shoichiro Nakao

789 **Sequential Balloon Technique in Angioplasty of Severe Coronary Arterial Obstructions.** David C. Levin, Lawrence M. Boxt, Richard Abben, J. Daniel Garnic, James M. Kirshenbaum, Dale Adler, Thomas Shook, Peter Friedman, and Peter Ganz

792 **Surgical Treatment of Medically Refractory Variant Angina Pectoris: Segmental Coronary Resection with Aortocoronary Bypass and Plexectomy.** Christopher DiPaolo, Nicholas Z. Kerin, Melvyn Rubenfire, and Frederick Levine

794 **Relation of Acute Myocardial Infarction to Cocaine Abuse.** Louis L. Cregler and Herbert Mark

794 **Coronary Arterial Findings After Accidental Death Immediately After Successful Percutaneous Transluminal Coronary Angioplasty.** Alan L. Soward, Catherina E. Essed, and Patrick W. Serruys

796 **Exercise-Related Bundle Branch Block in Children.** J. Timothy Bricker, Malinda S. Traweek, David A. Danford, Thomas A. Vargo, and Arthur Garson, Jr.

797 **Pacemaker Twiddler's Syndrome: An Important Cause of Diaphragmatic Pacing.** Anil Kumar, Charles R. McKay, and Shahbudin H. Rahimtoola

799 **Arrhythmogenic Right Ventricular Dysplasia in a Family.** Michael A. Ruder, Stuart A. Winston, Jesse C. Davis, Joseph A. Abbott, Michael Eldar, and Melvin M. Scheinman

800 **Induction and Termination of Ventricular Tachycardia by Changing Body Posture.** Tohru Ohe, Yosiaki Tomobuchi, and Katsuro Shimomura

802 **Norepinephrine Infusions in Congestive Heart Failure.** Steven R. Goldsmith, Gary S. Francis, and Jay N. Cohn

804 **Upright Paradoxical Posterior Wall Movement in Mitral Valve Prolapse.** Jack Krafchek, Mary Shaw, and Joseph Kisslo

806 **Safety of Labor and Delivery in Women with Mitral Valve Prolapse.** Edward P. Shapiro, Edward L. Trimble, J. Courtland Robinson, Myrna T. Estruch, and Sheldon H. Gottlieb

808 **Mitral Valve Prolapse and Addictions.** Jon Christopher Stringer, Anis Obeid, and Eleanor O'Shea

809 **Significance of E Point-Septal Separation by M-Mode Echocardiography in Patients with Aortic Regurgitation.** Maxine H. Rosoff and Michael V. Cohen

811 **Auscultation, M-Mode Echocardiography and Pulsed Doppler Echocardiography Compared with Angiography for Diagnosis of Chronic Aortic Regurgitation.** David G. Meyers, Terry S. Olson, and Dale A. Hansen

812 **Left Atrial Mobile Thrombus in Hypertrophic Cardiomyopathy.** Mareomi Hamada, Wataru Matsubara, Naoaki Tomita, Yusuke Miyauchi, and Tatsuo Kokubu

814 **Acute Left Ventricular Dysfunction and Thrombosis Following Natural Gas Poisoning.** Raymond P. Kelly and Dwain A. Owensby

815 **Massive Endocardial Calcification Associated with Endomyocardial Fibrosis.** Mária Lengyel, Attila Árvay, and Imre Palik

816 **Effect of Intense Aerobic Training on Exercise Performance in Children After Surgical Repair of Tetralogy of Fallot or Complete Transposition of the Great Arteries.** Linda M. Bradley, Frank M. Galioto, Jr., Paul Vaccaro, Denise A. Hansen, and Jane Vaccaro

818 **Coarctation of the Aorta Inherited as an Autosomal Dominant Trait.** Robert H. Beekman and Meinhard Robinow

821 **Two-Dimensional Echocardiographic Diagnosis of Total Anomalous Pulmonary Venous Connection Below the Diaphragm.** Pui-Kan Liao, Wen-Jen Su, and Jui-Sung Hung

822 **Computerized Tomography and Ultrasound in the Noninvasive Evaluation of Coarctation of the Aorta.** Maria Grazia Modena, Alberto Benassi, Giorgio Mattioli, Novella Guicciardi, Renato Romagnoli, and Giancarlo Canossi

825 **Arrhythmias and Left Ventricular Function in Chronic Alcoholics with Alcoholic Cirrhosis.** Roberto S. Gribaldo, Giulia S. Pomini, Filomena Sale, Giovanni Molfese, Leopoldo Costa, Paolo Maglio, and Giorgio Bozza

827 **Left Ventricular Thrombi in Association with Normal Left Ventricular Wall Motion in Patients with Malignancy.** Thomas S. DeGroat, R. Parameswaran, Paul M. Popper, and Morris N. Kotler

828 **Benign Intracardiac Thyroid Mass Causing Right Ventricular Outflow Tract Obstruction.** Richard J. Shemin, James D. Marsh, and Frederick J. Schoen

829 **Nonsurgical Treatment of the Superior Vena Cava Syndrome.** James H. Montgomery, Vincent J. D'Souza, Raymond B. Dyer, Augustin G. Formanek, and Sudhakar H. Prabhu

831 **Diagnosis of Cardiac Tumors in Infants by Magnetic Resonance Imaging.** Robert A. Boxer, Michael A. LaCorte, Sharanjeet Singh, James Shapiro, Miles Schiller, Mitchell Goldman, and Harry L. Stein

833 **Cardiac Hydatid Cyst Simulating Tricuspid Stenosis.** Çetin Erol, Isfendiyar Candan, Hakki Akalin, Ahmet Sonel, and Celal Kervancioğlu

834 **Echocardiographic Detection of Circulating Blood in Normal Canine Hearts.** Miguel A. Garcia-Fernandez, Jose Lopez-Sendon, Isabel Coma-Canella, and Jose Sotillo

The Original

...the only clinically-tested dipyridamole

Reliquary, for the heart of Anne of Brittany
Museum of Nantes

Crafted entirely in gold, the reliquary bears an eloquent inscription extolling the virtue of Anne, Duchess of Brittany and Queen of France. The reliquary dates from 1513.

dipyridamole

Tablets of 25, 50 and 75 mg

Persantine®

The experienced dipyridamole

BRIEF SUMMARY

INDICATIONS—Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency of, or eliminate, anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack. Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.
PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.
ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.
DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy. Tablets of 25, 50 and 75 mg. For complete details, please see the full prescribing information.

A new generation enters the field of cardiac diagnosis.

Ultrasound imaging has reached a new level of excellence. The Toshiba SSH-60A was designed to give the cardiologist maximum mobility and ease of operation. It's compact, lightweight and can be moved quickly to where it's needed.

We made the phased array probe smaller than ever, hereby reducing body surface contact to a minimum. With the Doppler unit, you can switch from pulsed to CW Doppler, using the same compact duplex probe. Easy flow diagnosis is achieved with the steerable Doppler beam from the duplex CW probe. A split screen monitoring lets you view B modes and Doppler spectra simultaneously, allowing diagnosis of blood flow abnormalities with great precision.

The SSH-60A is a versatile and – above all – cost-effective system in Toshiba's SSH-series, which includes the 65A, complete with the revolutionary color flow mapping system.

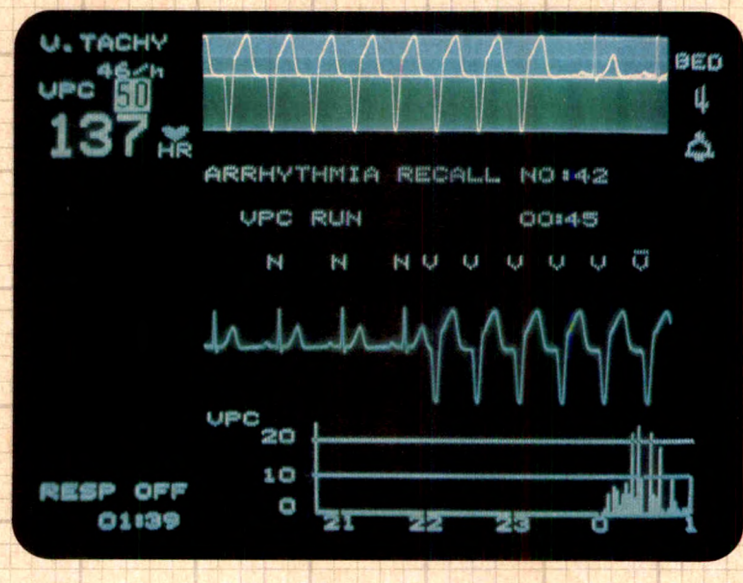
Lidocaine in the hospital.



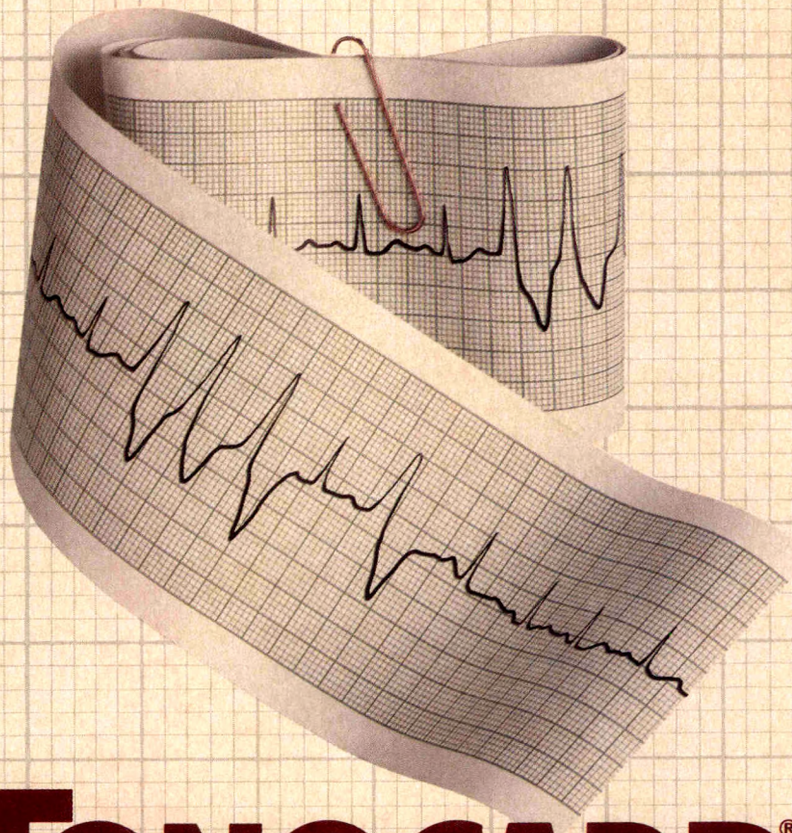
Like other antiarrhythmics, tocainide has not been shown to prevent sudden death, and also, like other antiarrhythmics, it has potentially serious adverse effects including the ability to worsen arrhythmias. Clinical and electrocardiographic evaluation should be used to periodically assess the need for therapy.

TONOCARD® (Tocainide HCl, MSD) is contraindicated in patients who are hypersensitive to this product or to local anesthetics of the amide type and in patients with second- or third-degree atrioventricular block in the absence of an artificial ventricular pacemaker.

Agranulocytosis, bone marrow depression, leukopenia, hypoplastic anemia, and thrombocytopenia have been reported in patients receiving TONOCARD; fatalities have occurred. Blood counts are recommended within the first two to three weeks of therapy and periodically thereafter. See Prescribing Information for details.

For a Brief Summary of Prescribing Information, please see last page of this advertisement.

TONOCARD in the office.



TONOCARD®
(TOCAINIDE HCl | MSD)

For symptomatic ventricular arrhythmias.

Like lidocaine. But it's oral.

TONOCARD
(TOCAINIDE HCl | MSD)

MERCK SHARP & DOHME

TONOCARD® (Tocainide HCl | MSD)

Like other antiarrhythmics, tocainide has not been shown to prevent sudden death in patients with serious ventricular ectopic activity, and also, like other antiarrhythmics, it has potentially serious adverse effects, including the ability to worsen arrhythmias. It is therefore essential that each patient given tocainide be evaluated electrocardiographically and clinically prior to, and during, tocainide therapy to determine whether the response to tocainide supports continued treatment.

CONTRAINDICATIONS

Patients who are hypersensitive to this product or to local anesthetics of the amide type.

Patients with second or third degree atrioventricular block in the absence of an artificial ventricular pacemaker.

WARNINGS

Blood Dyscrasias: Agranulocytosis, bone marrow depression, leukopenia, hypoplastic anemia and thrombocytopenia have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill and who were receiving concomitant drugs; fatalities have occurred. Since most of these events have been noted during the first 12 weeks of therapy, it is recommended that blood counts, including differential and platelet counts, be performed at least once within the first two to three weeks of therapy, and periodically thereafter, particularly within the first three months of therapy. Blood counts should be performed promptly if the patient develops any signs of infection (such as fever, chills, sore throat, or stomatitis), bruising, or bleeding. If any of these hematologic disorders is identified, TONOCARD should be discontinued and appropriate treatment should be instituted if necessary. Blood counts usually return to normal within one month of discontinuation. Caution should be used in patients with preexisting marrow failure or cytopenia of any type. (See ADVERSE REACTIONS).

Acceleration of Ventricular Rate: Acceleration of ventricular rate occurs infrequently when antiarrhythmics are administered to patients with atrial flutter or fibrillation (see ADVERSE REACTIONS).

PRECAUTIONS

General

Pulmonary Fibrosis: Pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. Many of these events occurred in patients who were seriously ill. The experiences are usually characterized by bilateral infiltrates on x-ray and are frequently associated with dyspnea and cough. Fever may or may not be present. Patients should be instructed to promptly report the development of any pulmonary symptoms such as exertional dyspnea, cough or wheezing. Chest x-rays are advisable at that time. If these pulmonary disorders develop, TONOCARD should be discontinued. (See ADVERSE REACTIONS).

In patients with known heart failure or minimal cardiac reserve, TONOCARD should be used with caution because of the potential for aggravating the degree of heart failure.

Caution should be used in the institution or continuation of antiarrhythmic therapy in the presence of signs of increasing depression of cardiac conductivity.

In patients with severe liver or kidney disease, the rate of drug elimination may be significantly decreased (see DOSAGE AND ADMINISTRATION).

Since antiarrhythmic drugs may be ineffective in patients with hypokalemia, the possibility of a potassium deficit should be explored and, if present, the deficit should be corrected.

Like all other oral antiarrhythmics, TONOCARD has been reported to increase arrhythmias in some patients (see ADVERSE REACTIONS).

Information for Patients

Patients should be instructed to promptly report the development of bruising or bleeding; any signs of infections such as fever, chills, sore throat, or soreness and ulcers in the mouth; or any pulmonary symptoms, such as exertional dyspnea, cough, or wheezing.

Laboratory Tests

As with other antiarrhythmics, abnormal liver function tests, particularly in the early stages of therapy, have been reported. Periodic monitoring of liver function should be considered. Hepatitis and jaundice have been reported in some patients.

Drug Interactions

Specific interaction studies with digoxin and metoprolol have been conducted, no clinically significant interaction was seen with digoxin, but tocainide and metaprolol had additive effects on wedge pressure and cardiac index. TONOCARD has also been used in open studies with digitalis, beta-blocking agents, other antiarrhythmic agents, anticoagulants, and diuretics, without evidence of clinically significant interactions. Nevertheless, caution should be exercised in the use of multiple drug therapy.

TONOCARD is equally effective in digitalized and non-digitalized patients. In 17 patients with refractory ventricular arrhythmias on concomitant therapy, serum digoxin levels (1.1 ± 0.4 ng/mL) remained in the expected normal range (0.5-2.5 ng/mL) during tocainide administration.

Pregnancy

Pregnancy Category C. In a teratogenicity study in rabbits, tocainide was administered orally at doses of 25, 50, and 100 mg/kg/day (about 1 to 4 times the usual human dose). No evidence of a drug-related teratogenic effect was noted; however, these doses were maternotoxic and produced a dose-related increase in abortions and stillbirths. In a teratogenicity study in rats, an oral dose of 300 mg/kg/day (about 12 times the usual human dose) showed no evidence of treatment-related fetal malformations, but maternotoxicity and an increase in fetal resorptions were noted. An oral dose of 30 mg/kg/day (about twice the usual human dose) did not produce any adverse effects.

In reproduction studies in rats at maternotoxic oral doses of 200 and 300 mg/kg/day (about 8 and 12 times the usual human dose, respectively), dystocia, and delayed parturition occurred which was accompanied by an increase in stillbirths and decreased survival in offspring during the first week postpartum. Growth and viability of surviving offspring were not affected for the remainder of the lactation period.

There are no adequate and well-controlled studies in pregnant women. TONOCARD should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers

It is not known whether tocainide is secreted in human milk. Because many drugs are secreted in human milk and because of the potential for serious adverse reactions in nursing infants from TONOCARD, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use

Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

TONOCARD commonly produces minor, transient, nervous system and gastrointestinal adverse reactions, but is otherwise generally well tolerated. TONOCARD has been evaluated in both short-term (n = 1,358) and long-term (n = 262) controlled studies as well as a compassionate use program. Dosages were lower in most of the controlled studies (1200 mg/day) and higher in the compassionate use program (1800 mg and more). In long-term (2-6 months) controlled studies, the most frequent adverse reactions were lightheadedness/dizziness (15.3 percent), nausea (14.5 percent), paresthesia/numbness (9.2 percent), and tremor (8.4 percent). These reactions were generally mild, transient, dose-related and reversible with a reduction in dosage, by taking the drug with food, or by therapy discontinuation. Tremor, when present, may be useful as a clinical indicator that the maximum dose is being approached. Adverse reactions leading to therapy discontinuation occurred in 21 percent of patients in long-term controlled trials and were usually related to the nervous system or gastrointestinal system.

Adverse reactions occurring in greater than one percent of patients from the short-term and long-term controlled studies appear in the following table:

	Percent of Patients Controlled Studies	
	Short-term (n = 1,358)	Long-term (n = 262)
NERVOUS SYSTEM		
Lightheadedness/dizziness/vertigo/giddiness	8.0	15.3
Paresthesia/numbness	3.5	9.2
Tremor/quivering/tremulousness	2.9	8.4
Confusion/disorientation/hallucinations	2.1	2.7
Altered mood/awareness	1.5	3.4
Restlessness/shakiness/nervousness	1.5	0.4
Blurred vision/visual disturbances	1.3	1.5
Discoordination/unsteadiness/walking disturbances	1.2	0.0
Anxiety	1.1	1.5
Tinnitus/hearing loss	0.4	1.5
Ataxia	0.2	3.0
Nystagmus	0.0	1.1
GASTROINTESTINAL SYSTEM		
Nausea	15.2	14.5
Vomiting	8.3	4.6
Anorexia	1.2	1.9
Diarrhea/loose stools	0.0	3.8
CARDIOVASCULAR SYSTEM		
Hypotension	3.4	2.7
Bradycardia	1.8	0.4
Palpitations	1.8	0.4
Chest Pain	1.6	0.4
Conduction disturbances	1.5	0.0
Left ventricular failure	1.4	0.0
OTHER		
Sweating/cold sweat/night sweats/clammy	5.1	2.3
Headache	2.1	4.6
Tiredness/drowsiness/fatigue/lethargy/lassitude/sleepiness	1.6	0.8
Hot/cold feelings	0.5	1.5
Rash/skin lesion	0.4	8.4

An additional group of about 2,000 patients has been treated in a program allowing for the use of TONOCARD under compassionate use circumstances. These patients were seriously ill with the large majority on multiple drug therapy, and comparatively high doses of TONOCARD were used. Fifty-four percent of the patients continued in the program for one year or longer, and 12 percent were treated for longer than three years, with the longest duration of therapy being nine years. Adverse reactions leading to therapy discontinuation occurred in 12 percent of patients (usually central nervous system effects or rash). A tabulation of adverse reactions occurring in one percent or more of patients follows:

	Percent of Patients Compassionate Use (n = 1,927)
NERVOUS SYSTEM	
Lightheadedness/dizziness/vertigo/giddiness	25.3
Tremor/quivering/tremulousness	21.6
Restlessness/shakiness/nervousness	11.5
Confusion/disorientation/hallucinations	11.2
Altered mood/awareness	11.0
Ataxia	10.8
Blurred vision/visual disturbances	10.0
Paresthesia/numbness	9.2
Nystagmus	1.1
GASTROINTESTINAL SYSTEM	
Nausea	24.6
Anorexia	11.3
Vomiting	9.0
Diarrhea/loose stools	6.8
CARDIOVASCULAR SYSTEM	
Increased ventricular arrhythmias/PVCs	10.9
CHF/progression of CHF	4.0
Tachycardia	3.2
Hypotension	1.8
Conduction disturbances	1.3
Bradycardia	1.0
OTHER	
Rash/skin lesion	12.2
Sweating/cold sweat/night sweats/clammy	8.3
Arthritis/arthralgia	4.7
Myalgia	1.7
Lupus	1.6

Adverse reactions occurring in less than one percent of patients in either the controlled studies or the compassionate use program or since the drug was marketed are as follows:

Nervous System: Coma, convulsions/seizures, depression, psychosis, mental change, agitation, altered taste/smell, difficulty concentrating, diplopia, dysarthria, impaired memory, increased stuttering/slurred speech, insomia/sleeping disturbance, local anesthesia, nightmares, thirst, weakness, myasthenia gravis.

Gastrointestinal System: Abnormal liver function tests, hepatitis, jaundice, (see PRECAUTIONS); stomatitis; abdominal pain/discomfort; constipation; dysphagia; gastrointestinal symptoms (including dyspepsia).

Cardiovascular System: Ventricular fibrillation, extension of acute myocardial infarction, cardiogenic shock, angina, AV block, hypertension, increased QRS duration, pleurisy/pericarditis, prolonged QT interval, right bundle branch block, syncope, vasovagal episodes, cardiomegaly, sinus arrest.

Pulmonary System: Respiratory arrest, pulmonary edema, pulmonary embolism, pulmonary fibrosis, fibrosing alveolitis, interstitial pneumonitis, pneumonia, dyspnea.

Other: Hematologic disorder (agranulocytosis, bone marrow depression, hypoplastic anemia, anemia, leukopenia, thrombocytopenia), increased ANA, urinary retention, polyuria/increased diuresis, alopecia, cinchonism, claudication, cold extremities, dry mouth, earache, edema, fever, hiccups, itching, leg cramps, malaise, metallic/menthol taste, muscle twitching/spasm, neck pain, pain radiating from neck, pallor/flushed face, pressure on shoulder, yawning.

Agranulocytosis, bone marrow depression, leukopenia, hypoplastic anemia, and thrombocytopenia have been reported (0.18 percent) in patients receiving TONOCARD in controlled trials and the compassionate use program. Many of these events occurred in patients who were seriously ill or who were receiving concomitant drugs; fatalities have occurred. Most of these events have been noted during the first 12 weeks of therapy. (See WARNINGS).

Pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia, possibly drug related, have been reported in patients receiving TONOCARD. The incidence of pulmonary fibrosis (including interstitial pneumonitis and fibrosing alveolitis) was 0.11 percent in controlled trials and the compassionate use program. These events usually occurred in seriously ill patients. Symptoms of these pulmonary disorders and/or x-ray changes usually occurred following 3-18 weeks of therapy and two patients died. (See PRECAUTIONS).

HOW SUPPLIED

Tablets containing 400 mg (scored) or 600 mg in bottles of 100 and unit-dose packages of 100.

J4T004-R 785 (DC7351504)

Someday all Holter recorders will be this small.

Spacelabs' technology makes it possible today.

Spacelabs has succeeded in putting all the power, capabilities and reliability of previous generations of Holter recorders into this 7.5 oz. recorder for the ultimate in patient convenience.

It's one more example of Spacelabs' continuing tradition of pioneering innovations that will become industry standards. It's tangible evidence of Spacelabs' commitment to bringing the latest technological advances into clinical practice to help you provide more cost-effective patient care.

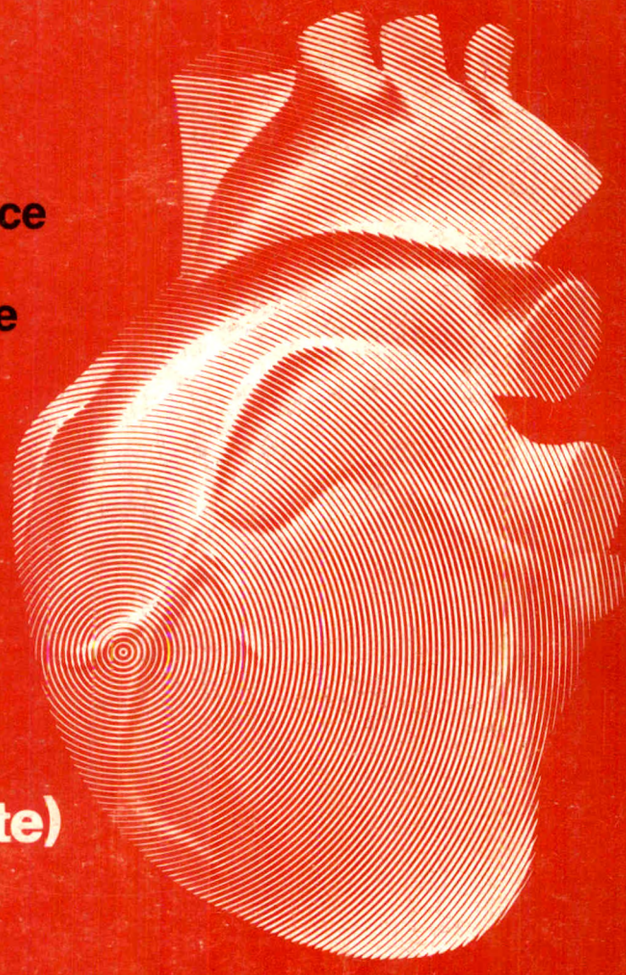
The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.



CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations.
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digoxin (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases where the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: The drug should be used with caution due to excretion of the quinidine in breast milk. ADVERSE REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/or disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTESTINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricular tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMATOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, and syncope; disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intense pruritus, urticaria. HYPERSENSITIVITY REACTIONS: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity. See package insert for Full Prescribing Information.

A Symposium: Role of Calcium Entry–Blocking Drugs in Hypertension

Introduction

EDWARD D. FROHLICH, MD

This 3-day symposium on "The Role of Calcium Entry–Blocking Drugs in Hypertension" brought together some of the leading investigators from around the world to discuss the latest advances in the field of hypertension therapy, including the applicability of calcium blockers.

The story of the calcium entry–blocking agents is remarkably similar to that of the β-blocking drugs. Although the first of the currently used β blockers appeared in 1964 (and it was even earlier for others), it was a long time before they were approved for the treatment of hypertension in the United States, some years after their approval for treatment of angina pectoris. In comparison, calcium antagonists were identified in 1962 as agents effective in treating acute hypertension. Their approval in the U.S. for angina followed 20 years later, and we are still awaiting approval for their use in hypertension.

The pioneer in delineating the properties of the calcium-channel blockers, Dr. Albrecht Fleckenstein, presented his recent work on the anticalcinotic (and antiarteriosclerotic) effects of calcium antagonists to begin the symposium. The effectiveness of calcium blockers as antihypertensive agents was the focus of several presentations. Dr. Fritz Buhler outlined the antihypertensive effects of these drugs, and pointed out that we have an additional calcium blocker—diltiazem—with which there is now considerable experience in the treatment of hypertension. As Dr. Barry Massie indicated, the calcium blockers verapamil, nifedipine and diltiazem are each comparable in efficacy to β blockers. Drs. Barry Materson and Marvin Moser and their colleagues showed that diltiazem was as effective as hydrochlorothiazide in treating hypertension in black patients. Drs. Robert O'Rourke and William Frishman cited studies showing that calcium antagonists are effective therapy for patients with hypertension and concomitant ischemic heart disease with angina pectoris.

Address for reprints: Edward D. Frohlich, MD, Vice President, Education and Research, Alton Ochsner Medical Foundation, 1516 Jefferson Highway, New Orleans, Louisiana 70121.

The role of the kidney in hypertension and in its treatment was another key topic discussed during the symposium. As Dr. Norman Hollenberg summarized, treatment strategies must take into account the renal response, because each class of antihypertensive drug has a different, and often limiting, effect on the kidney and vice versa.

The basic mechanism of action of the calcium blockers in hypertension—to dilate the blood vessels, thereby lowering blood pressure and reducing vascular resistance—is well understood. However, the discussions during this symposium have highlighted certain precautions. First, we must appreciate more clearly the cardiac effects of these agents—not only do they decrease vascular resistance, but they may also have a direct effect on the myocardium. Second, we must keep in mind the possible intracellular effect on protein synthesis by these agents as we learn the effect of these compounds in reducing cardiac mass. Third, we need greater sophistication in our understanding of

Edward D. Frohlich, MD

the intrarenal effects of the calcium-channel blockers. We still do not understand the mechanism of natriuresis—is it a hemodynamic effect, a redistribution of intrarenal flow or a result of selective cellular effects within the kidney? The concept of intrarenal flow distribution, as it relates to excretion of uric acid, sodium or even calcium may also be important.

Several interesting concepts have been introduced in this symposium that will undoubtedly be expanded upon in subsequent years. The prevention of calcinosis is intriguing, and its possible role in atherogenesis deserves further study. The relation of calcium blockers to spasm, especially cerebral vasospasm, was discussed by Drs. John and Rosemary Bevan. The interrelation of calcium and magnesium, and their effect on hormonal systems and on the intracellular effects of calcium, clearly need further definition. Finally, the possibility that certain concentrations of calcium either stimulate or inhibit protein synthesis was examined, along with the possible selective effect on the myocardium; both of these concepts merit further investigation.

The opportunity to exchange up-to-the-minute data in a field that is continuously changing is essential. The participants in this symposium certainly appreciated such an opportunity, and it is hoped that the reader will find the information compiled in this symposium supplement interesting and useful.

Experimental Basis of the Long-Term Therapy of Arterial Hypertension with Calcium Antagonists

ALBRECHT FLECKENSTEIN, MD, MARKUS FREY, MD, JÜRGEN ZORN, MD, and GISA FLECKENSTEIN-GRÜN, MD

In vascular smooth muscle (as in myocardial fibers) a transmembrane supply of Ca^{++} ions is required for active tension development. In consequence, Ca^{++} antagonists, which restrict transmembrane Ca^{++} delivery, possess a wide scope of action against practically all types of vasoconstrictor or spastic reactions on coronary, pulmonary, cerebral, renal or mesenteric arteries. Another important target of Ca^{++} antagonists is the resistance vessels of systemic circulation in both animals and humans. Thus, Ca^{++} antagonists are successfully used for the treatment of acute hypertensive crises as well as for long-term antihypertensive therapy.

Spontaneously hypertensive rats (SHRs) also respond to suitable Ca^{++} antagonists with a dramatic fall in blood pressure. The acute spasmolytic effects of Ca^{++} antagonists can be directly visualized by ophthalmoscopic examination of the arterioles in the ocular fundus. In untreated SHRs these arterioles are always heavily constricted, and aneurysm-like luminal protuberances develop. In contrast, after 1 adequate Ca^{++} antagonist dose, blood pressure instantaneously falls to its normal level while the retinal arterioles dilate.

A further important effect of Ca^{++} antagonists that we have demonstrated in experiments on SHRs is the prevention of progressive arterial Ca^{++} overload, which otherwise produces severe calcinotic or arteriosclerotic damage of the arterial walls. However, with the help of Ca^{++} antagonists, arterial integrity can be totally preserved. Interestingly, this anticalcinotic arterial protection by Ca^{++} antagonists may also manifest itself independent of any blood pressure change. This is true of arterial calcinosis in normotensive rats because of advanced age, alloxan diabetes or intoxication with overdoses of vitamin D_3, dihydrotachysterol or nicotine.

(Am J Cardiol 1985;56:3H–14H)

Excitation is a superficial process at the cell membrane, whereas contraction is an intracellular phenomenon. Therefore, there is a need for some kind of information transfer from the fiber surface to the internal contractile elements if the excitatory events are to be strictly linked with mechanical reactions. As is particularly obvious from observations on myocardial fibers and vascular smooth muscle cells, nature has solved this difficult problem with the help of Ca^{++} ions, which serve as messengers. During the past decade, definite evidence has been obtained in cardiac muscle of the existence of a special transmembrane carrier system for Ca^{++} ions, i.e., the so-called slow channels that open if the resting potential breaks down.

In consequence, a transmembrane influx of activator Ca^{++} sets in during cardiac excitation, together with a liberation of Ca^{++} from certain sarcoplasmic stores. The resulting increase in the intracellular concentration of free Ca^{++} ions initiates the splitting of adenosine triphosphate (ATP) by the Ca^{++}-dependent myofibrillar adenosine triphosphatase. In this way phosphate-bond energy is transformed into mechanical work. Various positive inotropic agents, e.g., adrenergic β-receptor stimulants, potentiate the transmembrane influx of Ca^{++} during cardiac excitation. In this way, they intensify both splitting of ATP and contractile force, while oxygen requirement for the subsequent ATP resynthesis increases. Conversely, every restriction of transmembrane Ca^{++} supply by simple extracellular Ca^{++} withdrawal, or by agents

A comprehensive synopsis of these studies has recently been given by Fleckenstein.[1] The experimental studies were supported by grants from the Federal Ministry for Scientific Research and Technology, Bonn, Federal Republic of Germany.

that inhibit transmembrane Ca^{++} influx through the slow channels, reduces high-energy phosphate consumption and contractile tension development as well as oxygen demand.

In the early 1960s Fleckenstein studied several drugs that were able to modify the Ca^{++}-dependent contractile energy expenditure of the ventricular myocardium.[1–8] In the course of these investigations, the new pharmacologic family of "calcium antagonists" was found. These drugs block the slow-channel–mediated transmembrane Ca^{++} entry into the excited cardiac fibers in a highly specific way.[1,5,9] In addition, the existence of an analogous transmembrane carrier system for Ca^{++} ions was established in visceral and vascular smooth muscle. Interestingly enough, the sensitivity of the arterial vasculature to the inhibitory actions of the Ca^{++} antagonists proved to be even greater than that of the myocardium.[1,4,10–13]

Figure 1 shows the most important Ca^{++} antagonists identified by Fleckenstein and co-workers since 1964 on the basis of various electrophysiological, biophysical and biochemical tests.[1–7,9,14,16] Only diltiazem was added to this new pharmacologic family in 1975 by Japanese investigators.[15]

The Ca^{++} antagonists should be subdivided according to the profile of their actions on myocardial fibers into 2 groups. The first group, which we call group A, comprises the most potent and specific Ca^{++} antagonists such as verapamil, D 600 (the new generic name for D 600 is gallopamil), diltiazem, nifedipine and its derivatives niludipine, nimodipine, ryosidine and other 1,4-dihydropyridine compounds (Fig. 2). We have

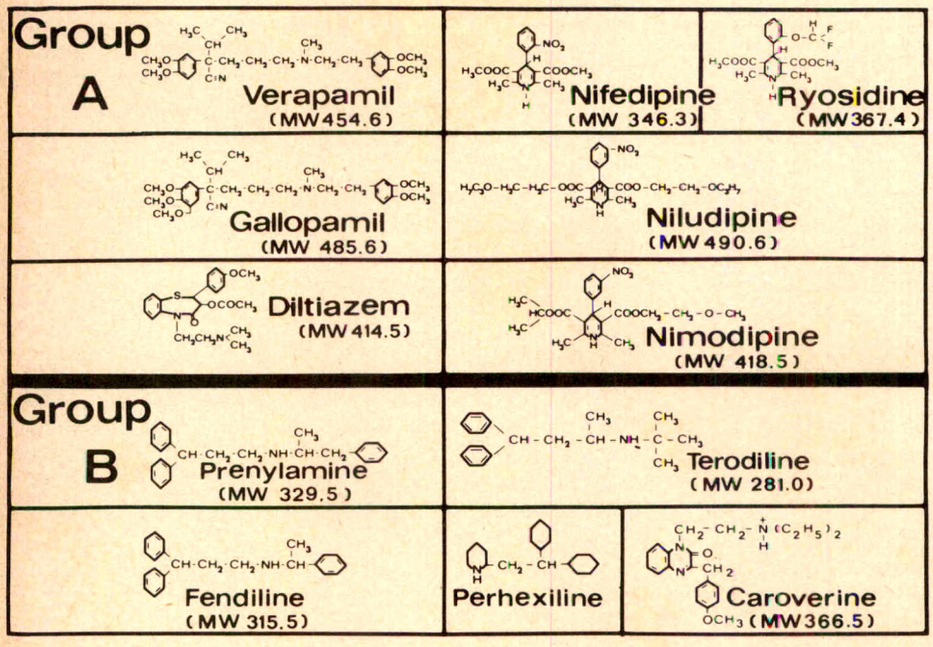

FIGURE 1. Specific calcium antagonists first identified in the Physiological Institute, Freiburg University (with the exception of diltiazem). For particular references see Fleckenstein.[1]

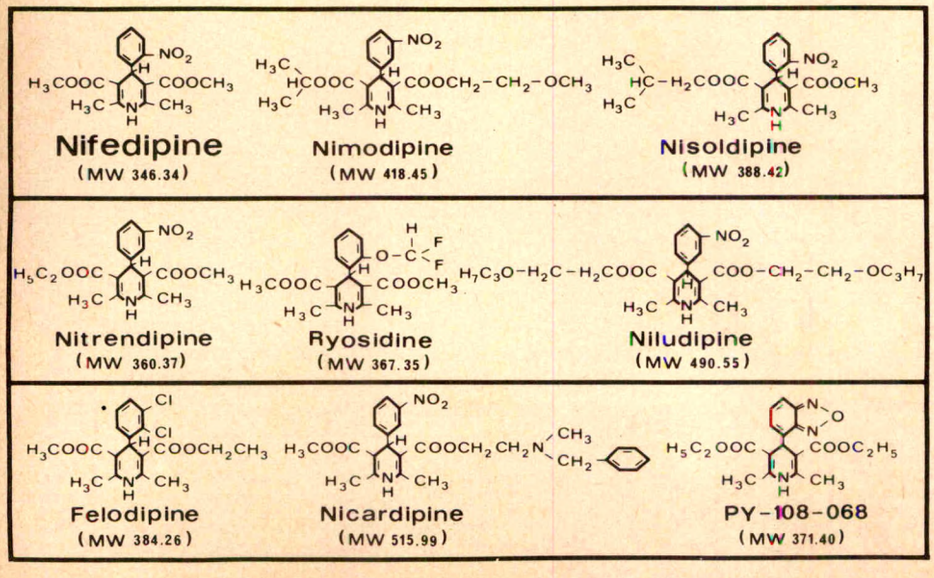

FIGURE 2. Highly specific 1,4-dihydropyridine calcium antagonists derived from the prototypical substance nifedipine. Nifedipine was identified in our laboratory as a top calcium antagonist in 1969/1970.[1–5,10,13,14,16] The code name was "Bay a 1040"; the usual trade name in Europe is "Adalat."

shown that the substances in group A are capable of inhibiting Ca^{++}-dependent excitation–contraction coupling of heart muscle by 95% and more, before the sodium and magnesium conductivities of the excited myocardial sarcolemma membrane are also affected.

Group B, on the other hand, includes prenylamine, terodiline, fendiline, perhexiline, caroverine and many other agents. The drugs of group B are somewhat less potent and less specific than those of group A, because they also inhibit the fast-channel–mediated sodium influx during the rising phase of action potential, if the inward Ca^{++} current has been lowered by 50 to 70%. In addition, the agents in group B are unable to discriminate between certain Ca^{++}- and magnesium-dependent bioelectric membrane effects; in contrast, the Ca^{++} antagonists in group A suppress the Ca^{++}-carried phenomena selectively.[1] Therefore, this discussion focuses on the Ca^{++} antagonists of group A, particularly verapamil, nifedipine and diltiazem. Moreover, this article deals preferentially with the manifestations of Ca^{++} antagonism on *vascular contractility*, which is certainly the most important target of Ca^{++} antagonists, at least with respect to the particular topic of this supplement.

In fact, the Ca^{++} antagonists of group A are the most efficient agents for suppression of vascular hyperactivity, which underlies excessive tone or spasms in various arteries of the coronary, pulmonary, cerebral, renal or intestinal circulation. Moreover, because these Ca^{++} antagonists strongly relax the systemic resistance vessels they also exhibit outstanding antihypertensive effects in both animals and humans.

Antihypertensive Effects of Calcium Antagonists

Significance of transmembrane calcium supply for activation of systemic resistance vessels: How do the Ca^{++}-antagonistic drugs interfere with contractile activation of vascular smooth muscle? Taking coronary smooth muscle as an example, Figure 3 shows that there are 2 physiologic sources of activator Ca^{++} for vasoconstriction. Probably the most important pathway (I) by which Ca^{++} is supplied for contractile activation consists of a potential or receptor-dependent Ca^{++} influx through plasma membrane channels, as shown in the upper half of Figure 3. Alternating electric square wave stimulation, depolarization with high extracellular potassium, quick stretch, cardiac glycosides and coronary vasoconstrictor agonists such as acetylcholine, serotonin and histamine, as well as noradrenaline (after previous β-receptor blockade), open these transmembrane Ca^{++} channels. The resulting contractile responses are of tonic character and are most responsive to the inhibitory action of Ca^{++} antagonists. The second alternative pathway (II) is shown in the lower half of Figure 3. Here Ca^{++} can be released from cellular storage sites by "receptor-operated" nonelectric mechanisms. The resulting contractile responses to this cellular Ca^{++} release are of phasic character. Ca^{++} withdrawal or Ca^{++} antagonists do not directly impair the Ca^{++} release from cellular depots, but inhibit (in a somewhat higher concentration) transmembrane replenishment of the Ca^{++} stores after Ca^{++} release.

In considering the 2 alternative pathways, it becomes obvious that the pattern of contractile activation of the systemic resistance vessels corresponds best with the transmembrane type (I) of Ca^{++} supply, which also predominates in the vasculature of the extramural coronary stem arteries. Thus, there is a striking similarity between the behavior of coronary smooth muscle and of the systemic resistance vessels.[1,10,12,13] For example:

1. Both extramural coronary wall tension and systemic flow resistance are highly responsive to changes in the extracellular Ca^{++} concentration. More precisely, if the transmembrane Ca^{++} supply from extracellular sources is interrupted by simple Ca^{++} withdrawal or by Ca^{++} antagonists, coronary

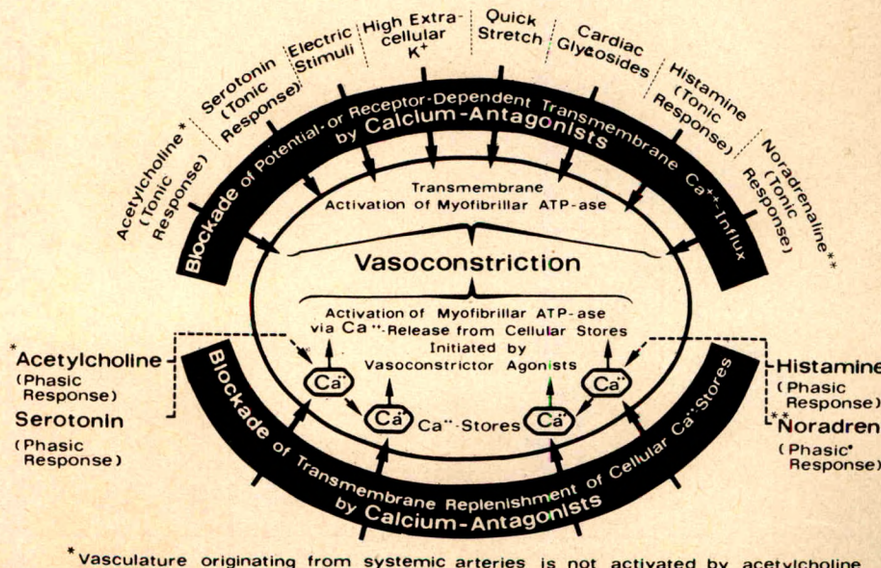

FIGURE 3. Scheme of the dual source of activator Ca^{++} for the tonic and phasic vascular smooth muscle contractions; i.e., (I) potential-or receptor-dependent transmembrane Ca^{++} supply for tonic responses, and (II) release of Ca^{++} from cellular stores for phasic responses to vasoconstrictor agonists. The Ca^{++} antagonists directly and most effectively inhibit transmembrane Ca^{++} influx, i.e., pathway I. However, to a lesser extent Ca^{++} antagonists also interfere with pathway II, probably indirectly by impairing transmembrane replenishment of cellular Ca^{++} stores. The exact anatomical location of these cellular Ca^{++} stores is a pending problem. Reprinted from Fleckenstein.[1]

*Vasculature originating from systemic arteries is not activated by acetylcholine

**Noradrenaline produces contraction of extramural coronary vasculature only after previous β-receptor blockade

tension development and systemic arteriolar tone break down.

2. In both coronary smooth muscle and systemic resistance vessels, there is a strong natural competition between Ca^{++} and hydrogen ions and a high sensitivity to any change in their ratio. Therefore, accumulation of hydrogen ions, in cases of local or general acidosis, always produces vasodilation by counteracting Ca^{++} ions. Conversely, alkalosis, by lowering the hydrogen ion concentration, potentiates the vasoconstrictor effects of Ca^{++} ions.[1,11,17,18] In all probability, hydrogen ions inhibit transmembrane Ca^{++} entry in coronary arteries and resistance vessels, and also interfere with the Ca^{++}-dependent internal activation of myofibrillar adenosine triphosphatase.

3. At a constant, normal pH, excessive Ca^{++}-dependent tone of the coronary vasculature and the systemic resistance vessels can best be lowered by the use of Ca^{++} antagonists. Interestingly enough, the Ca^{++} antagonists of group A with the strongest vasodilator effects on the coronary vasculature also reduce the flow resistance in systemic circulation with a similarly high efficacy.

Experimental evidence of therapeutic blood pressure control with calcium antagonists: The long series of clinical investigations on the antihypertensive effects of Ca^{++} antagonists began with verapamil even before the Ca^{++}-antagonistic mechanisms of action of this drug had been generally recognized. Apart from early experimental observations in our laboratory,[8] 4 clinical research groups directed by Heidland,[19] Brittinger et al,[20] Bender[21] and Belz[22] carried out the first therapeutic trials in different German clinics in the middle and late 1960s, independent of one another. They were particularly interested in the *acute* antihypertensive effects of verapamil. Brittinger and co-workers realized the usefulness of verapamil in the treatment of hypertensive crises.[20] Moreover, Japanese physicians in the early 1970s recognized the therapeutic value of verapamil in chronic hypertension as well and applied it for stroke prophylaxis.

A detailed analysis of the Ca^{++} dependency of coronary and systemic vascular resistance and its acute attenuation by the Ca^{++} antagonists verapamil, gallopamil and nifedipine was published in 1972 by Grün and Fleckenstein.[13] Subsequently, in order to visualize the antihypertensive effects of verapamil[23] and other Ca^{++} antagonists in long-term studies, we treated spontaneously hypertensive rats (SHRs) with daily oral doses for 4 to 18 months. The therapy was always started at the age of 1 month. As can be seen from the upper curve in Figure 4, hypertensive rats that were not given a Ca^{++} antagonist showed an increase of blood pressure of nearly 100% within 5 months, up to approximately 200 mm Hg. In contrast, hypertensive rats treated with verapamil behaved like normotensive control Wistar Kyoto rats (WKYs) of the same age—the blood pressure of the verapamil-treated rats (represented by the hatched curve) remained at the low level of 110 mm Hg. However, when the therapy was discontinued, arterial blood pressure rapidly rose within a day to the high level of untreated hypertensive rats.

Nifedipine and other Ca^{++}-antagonistic 1,4-dihydropyridine derivatives have also been shown in our studies to exert antihypertensive actions. This applies

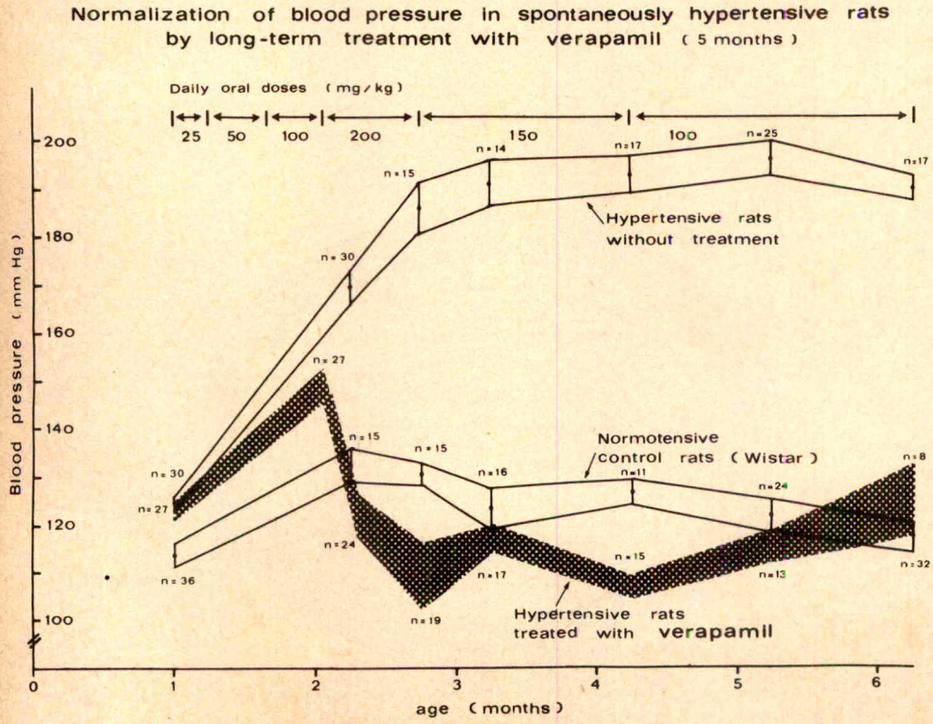

FIGURE 4. Normalization of mean arterial blood pressure of spontaneously hypertensive rats by chronic oral administration of verapamil for 5 months. Treatment lasted from the end of the first to the end of the sixth month of age. Data from von Witzleben et al.[23] (See Fleckenstein-Grün and Fleckenstein.[12])

for nifedipine, nimodipine, nisoldipine, nitrendipine, niludipine, ryosidine, felodipine and nicardipine. Diltiazem also belongs to this class of antihypertensive Ca^{++} antagonists. Figure 5 represents observations obtained from SHRs. Here, normalization of blood pressure was achieved by acute oral treatment with diltiazem, after hypertension of more than 200 mm Hg had been fully maintained for at least 14 months during a previous observation period of 19 months. This experiment shows a true therapeutic effect, in contrast to the antihypertensive prophylaxis in the foregoing studies.

In recent years, nifedipine and other Ca^{++} antagonists have also been shown to exert antihypertensive actions in other disease models. For instance, normalization of high blood pressure by chronic treatment with nifedipine was also observed in sodium-loaded, salt-sensitive Dahl rats.[24] Similarly, conscious renal-hypertensive dogs are rather responsive to Ca^{++} antagonists. As shown by Hiwatari and Taira,[25] an acute fall of blood pressure could be obtained in these animals with 1 oral dose of niludipine 1 to 3 mg/kg. Diltiazem also proved to be effective in the treatment of spontaneously hypertensive, renal-hypertensive and desoxycorticosterone/saline-loaded hypertensive rats.[26]

Parallel suppression of hypertension and arterial calcium overload with calcium antagonists: According to our observations with the Ca^{++} antagonists of group A, a strong antihypertensive action is common to all these agents. Differences in strength can usually be compensated for by adjusting the dose. Another effect shared by all antihypertensive Ca^{++} antagonists of group A is the prevention of excessive Ca^{++} accumulation in the arterial walls.[1,12,27–30] In untreated hypertensive rats, the Ca^{++} content of the arterial walls steadily rises until, at an age of 18 to 20 months, it may reach a value that is approximately 2 to 3 times as high as in normotensive control WKYs of the same age. However, using Ca^{++} antagonists, both blood pressure and arterial Ca^{++} content could be kept at normal levels seen in these long-term experiments. Figure 6 shows a series of observations on SHRs with or without prophylactic oral administration of nitrendipine. In fact, corresponding to the complete prevention of hypertension over an observation period of 18 months, there was also *no* abnormal increase in the Ca^{++} content of the aortic and mesenteric arterial walls. In none of these experiments with Ca^{++} antagonists of group A have we found any dissociation between their antihypertensive and their anticalcinotic actions.

Prevention of severe arteriolar constriction and arterial damage by long-term treatment of spontaneously hypertensive rats with calcium antagonists: In SHRs, which are generally regarded to resemble human patients with essential hypertension,

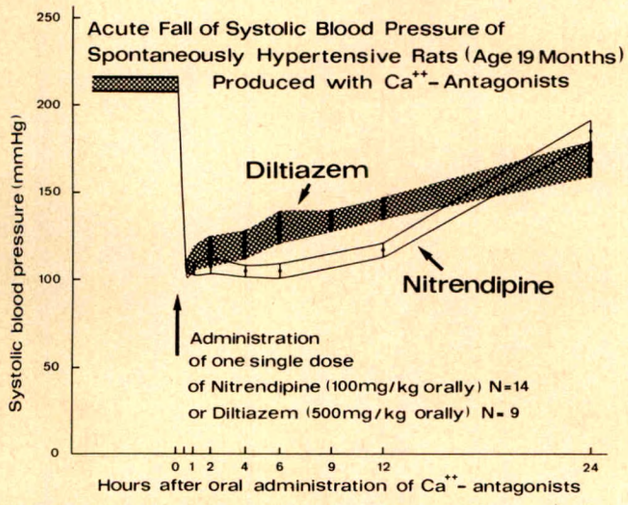

FIGURE 5. Instantaneous normalization of arterial blood pressure of 19-month-old spontaneously hypertensive rats after oral administration of 1 dose of nitrendipine (n = 14) or diltiazem (n = 9). Before administration of nitrendipine or diltiazem, the spontaneously hypertensive rats had maintained a blood pressure level >200 mm Hg for at least 14 months (see Fig. 6A, upper curve). In response to the Ca^{++} antagonists, the arteriolar spasm in the ocular fundus disappeared simultaneously with the acute fall in blood pressure, whereas the aneurysms persisted. Spontaneously hypertensive rats, at an age <12 months, tolerated the acute lowering of blood pressure without undesired adverse effects. Two heavily arteriosclerotic 19-month-old rats (out of 23) died within 24 hours after administration of the Ca^{++} antagonists.

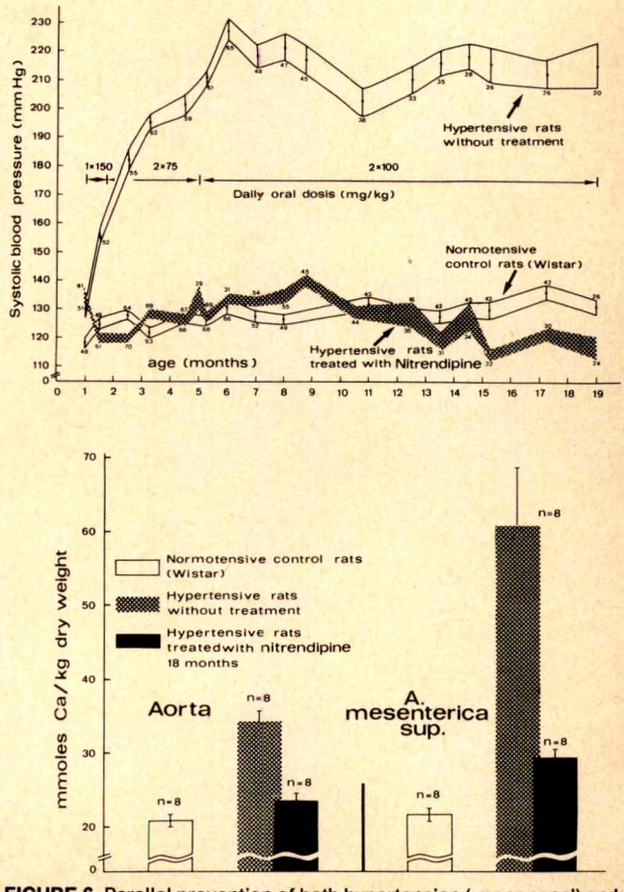

FIGURE 6. Parallel prevention of both hypertension (upper panel) and Ca^{++} overload of the aortic and mesenteric walls (bottom panel) by prophylactic oral treatment with nitrendipine over 18 months.

the increase in systemic arteriolar tone can be visualized directly by examination of the ocular fundus. As already known from observations by Takahashi,[31] the caliber of the retinal arterioles diminishes in SHRs during the period of progressive blood pressure elevation. In consequence, the ratio of the caliber of the retinal arterioles to that of the veins, which is normally around 1:2, changes considerably. In our studies, the arteriolar diameter in the state of fully developed hypertension was only about one-fourth of that of the accompanying retinal veins (Fig. 7A and B). However, apart from uniform spastic constriction, irregularities of the arteriolar diameter appear in the form of indentations, aneurysmal dilations or "rosary-like" alternations of extremely narrowed and expanded sections. There is a clear time-dependent progression of these luminal irregularities in that the ocular arterioles of 3-month-old hypertensive rats only exhibited a uniform constriction, whereas at a later stage, the occurrence of aneurysm-like protuberances became more frequent.

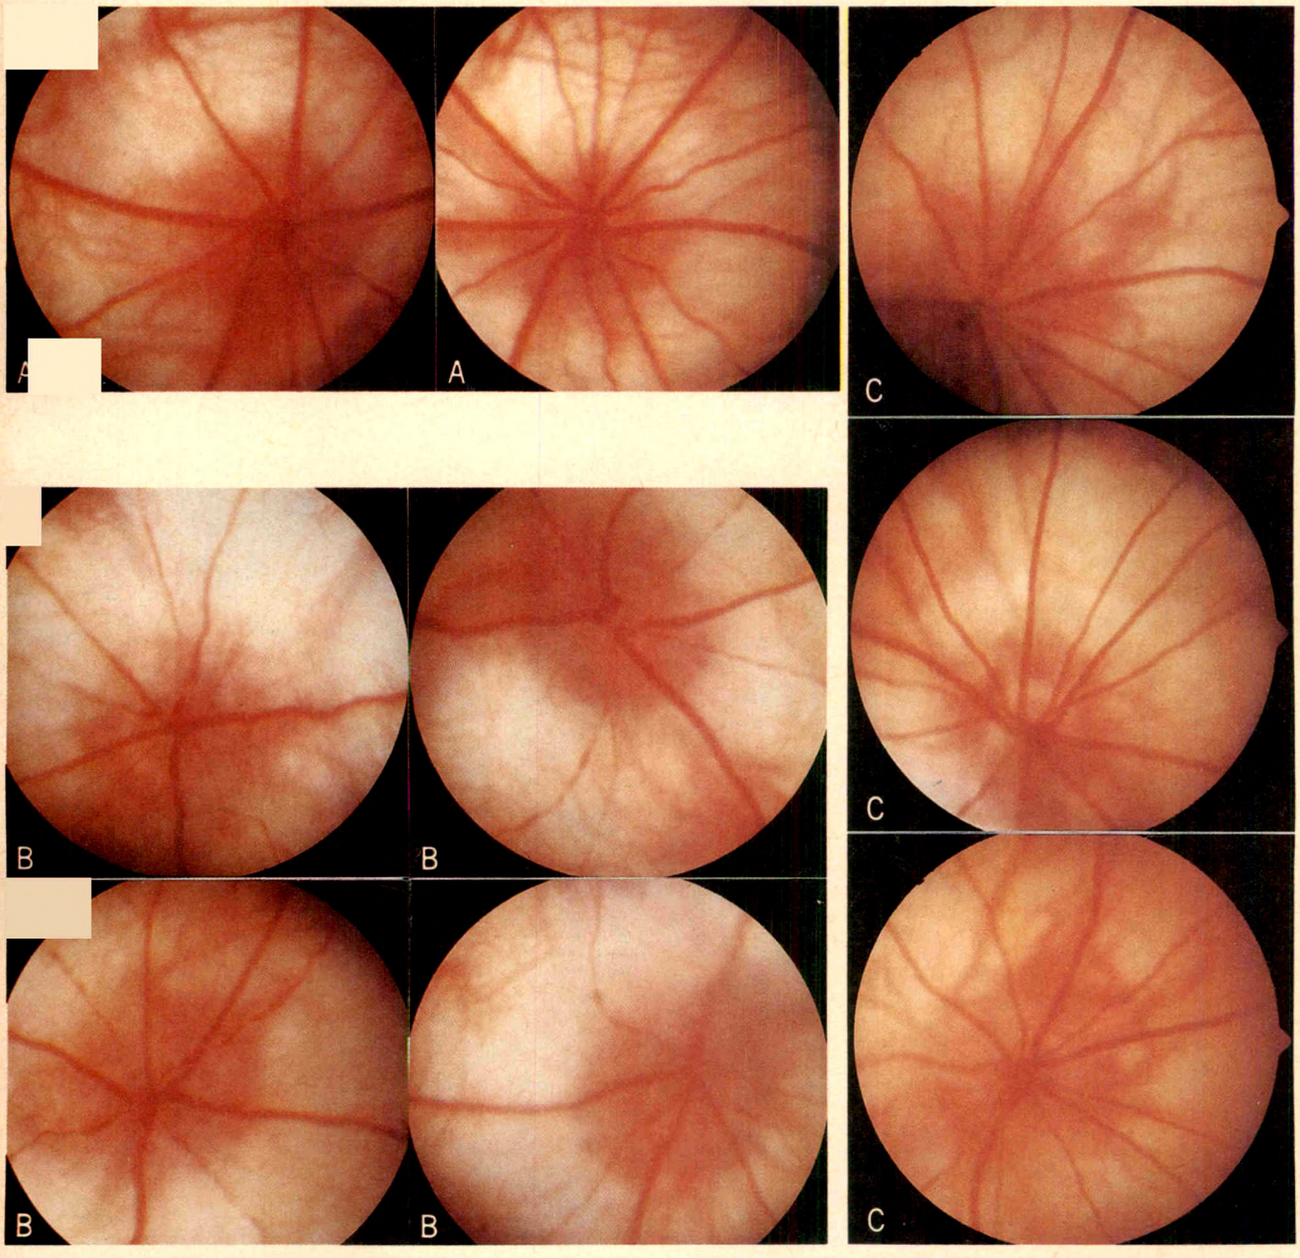

FIGURE 7: A, Normal ocular fundus of nonhypertensive WKY control rat. Note the veins (large diameter) and the arterioles (smaller diameter). **B,** Severe arteriolar vasoconstriction and development of aneurysm-like caliber irregularities in untreated 19-month-old spontaneously hypertensive rats. There is absence of discernible alterations in width and structure of the veins. **C,** Complete prevention of arteriolar spasm and aneurysm-like caliber irregularities in 19-month-old spontaneously hypertensive rats by long-term treatment with Ca^{++} antagonists over 18 months. **Top,** Treated with daily oral dose of verapamil (100 to 150 mg/kg) in diet calculated from food consumption. **Middle,** Treated with daily dose of nitrendipine (2 × 100 mg/kg) via stomach tube. **Bottom,** Treated with daily dose of nisoldipine (2 × 100 mg/kg) via stomach tube.

Accordingly, our ophthalmoscopic photographs of the ocular fundus of several series of untreated 19-month-old hypertensive rats revealed an incidence of aneurysm-like caliber irregularities of 75 to 85%.

With the use of Ca^{++} antagonists, however, all these severe arteriolar changes could be totally prevented in the overwhelming majority of hypertensive rats (Fig. 7C). In fact, the ocular arterioles of 60 Ca^{++}-antagonist–treated SHRs kept in the physiologic blood pressure range over 18 months showed no constriction, and showed minor luminal irregularities in only a few cases. The order of protective potency of the Ca^{++} antagonists tested to date over 18 months is nitrendipine = nisoldipine >verapamil (Fig. 8).

It is interesting to note that, even in the late stage of untreated hypertension, the 19-month-old animals still responded to single oral doses of Ca^{++} antagonists (100 mg/kg of nifedipine or nitrendipine) not only with a steep fall in blood pressure, but also with a rapid dilation of the constricted ocular arterioles. However, the aneurysm-like luminal protuberances did not disappear acutely. This indicates that a large part of the arteriolar narrowing in the ocular fundus is of spastic rather than sclerotic nature, whereas the aneurysms probably reflect a more pronounced structural alteration of the arteriolar walls.

In untreated hypertensive rats, larger arteries with thicker media always undergo still more spectacular changes than do the ocular arterioles. In other words, approximately the same time at which the arterioles develop aneurysms, the larger arteries exhibit arteriosclerosis. This is most dramatic in the mesenteric artery and its branches. Here severe media calcification with enormous wall thickening, partial or total luminal obliteration and ischemic damage of the gut were common findings (Fig. 9A and B). Again, all these pathologic changes of the arterial wall structure could be totally prevented by our Ca^{++}-antagonistic long-term prophylaxis over 18 months (Fig. 9C). Interest-

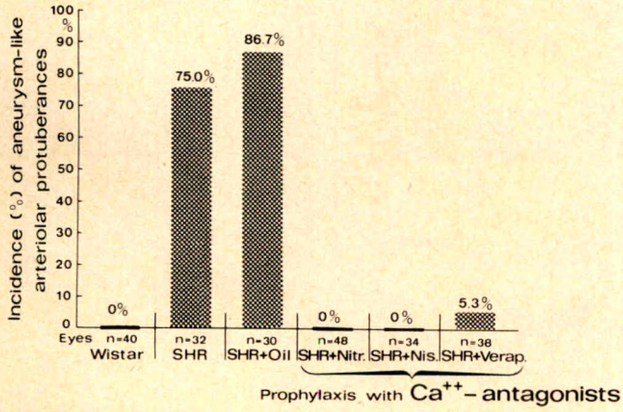

FIGURE 8. Ophthalmoscopic assessment of aneurysm-like luminal irregularities of the retinal arterioles in 19-month-old normotensive control Wistar Kyoto rats, in 19-month-old spontaneously hypertensive rats (SHRs) without Ca^{++}-antagonist treatment and in 19-month-old SHRs at the end of prophylactic administration of nitrendipine (Nitr.), nisoldipine (Nis.) or verapamil (Verap.) over 18 months. Incidence (%) = the number of eyes with arteriolar protuberbances in the ocular fundus in relation to the total number of eyes in each group. Because the SHRs were given nitrendipine and nisoldipine in an oil solution, an additional control group of 30 SHRs was formed in which the animals received corresponding quantities of pure oil without nitrendipine and nisoldipine ("oil") over 18 months.

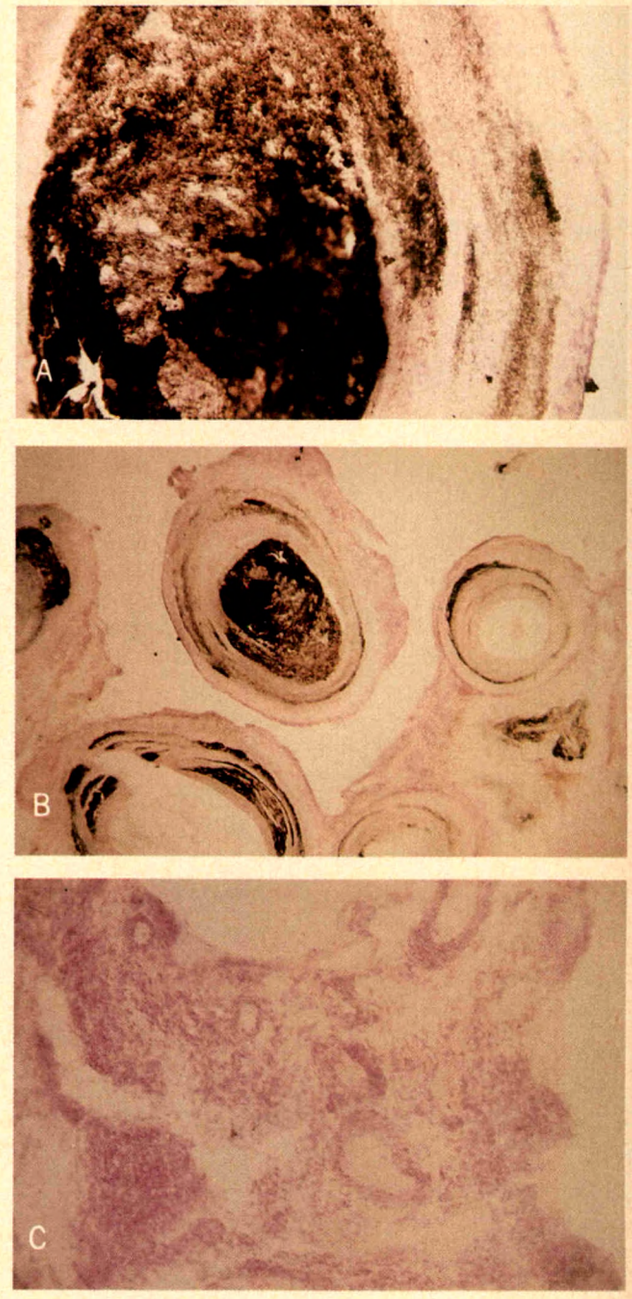

FIGURE 9. Antiarteriosclerotic long-term protection of spontaneously hypertensive rats (SHRs) demonstrated in the mesenteric artery and its branches. **A** and **B,** SHRs *without* Ca^{++}-antagonist treatment over 19 months. Without prophylaxis, complete or partial obliteration of the arterial lumen occurs in most mesenteric vessels. Simultaneously, calcific encrustations and enormous thickening of the arterial walls regularly develop. **C,** SHR after prophylactic long-term treatment with nitrendipine (2 × 100 mg/kg orally/day) over an observation period of 18 months. Complete preservation of structural integrity, i.e., no calcification, luminal narrowing or wall thickening of the mesenteric artery and its branches. Among a total of 60 Ca^{++}-antagonist-protected SHRs, there was no significant arterial damage. For visualization of tissue calcium as black areas, von Kossa's technique was applied, followed by additional staining with Nuclear Fast Red (Merck).

ingly, the mesenteric arterial walls, which always accumulate particularly great amounts of Ca^{++} during untreated hypertension (Fig. 6), also underwent the most dramatic morphologic alterations ever seen in our studies on hypertensive rats. Conversely, the antiarteriosclerotic prophylaxis with Ca^{++} antagonists was most obvious in this particular section of systemic circulation.

Prevention of Experimental Arteriosclerosis by Calcium Antagonists in Normotensive Rats

There is ample evidence that the anticalcinotic or antiarteriosclerotic efficacy of Ca^{++} antagonists is not only a simple consequence of their antihypertensive action, but may also manifest itself independently of any appreciable blood pressure change. Our first results were reported in 1971 in a presentation entitled "Inhibition of arteriosclerotic vascular lesions by prophylactic treatment with $MgCl_2$, KCl and organic Ca^{++} antagonists: quantitative studies with ^{45}Ca in rats."[32] Since then we have incessantly called attention to the vasoprotective properties that Ca^{++} antagonists can exert experimentally against various types of Ca^{++}-induced arterial damage. Our studies[1,28–30,32,33] led to the unconventional working hypothesis that excessive Ca^{++} incorporation into the arterial walls is a primary causative factor in the pathogenesis of arteriosclerosis, rather than merely a concomitant or subsequent phenomenon. Thus, we have found that all major risk factors that favor human arteriosclerosis (advanced age, diabetes, hypertension, excessive doses of dihydrotachysterol, vitamin D_3 and nicotine) are capable of enhancing arterial Ca^{++} uptake in healthy rats, and thereby facilitate or produce severe calcific alterations of the arterial walls. Conversely, suitable Ca^{++} antagonists have proved capable of protecting the arterial walls against calcinosis and structural damage. If such risk factors are acting in combination (for instance, nicotine plus vitamin D_3), tremendous degrees of deleterious arterial Ca^{++} accumulation can be attained within a few days in spite of little or no increase in blood pressure.

Figure 10A demonstrates the outstanding efficacy of diltiazem in inhibiting vitamin D_3-induced coronary calcinosis. Under the influence of vitamin D_3 alone, the Ca^{++} content of the coronary wall tissue of rats rose from 12 to 220 mmol/kg dry weight. With diltiazem, the effect of vitamin D_3 was completely neutralized.

To visualize the prevention of experimental coronary calcinosis by Ca^{++} antagonists, we also made use of histochemical techniques, particularly von Kossa's

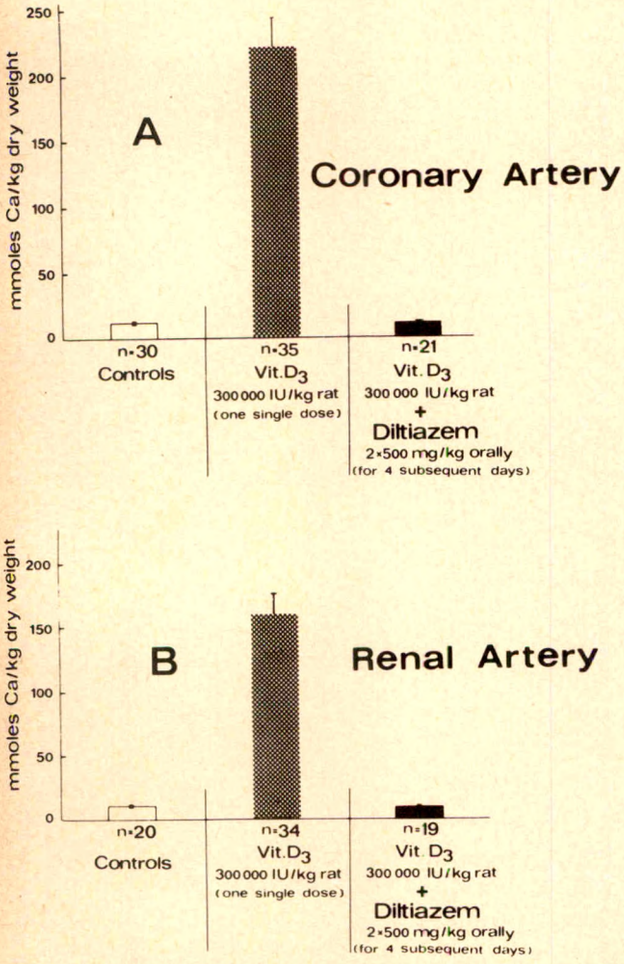

FIGURE 10. A, Oral administration of 2 × 500 mg diltiazem/kg body weight to rats for 4 consecutive days completely neutralizes the tremendous stimulation of Ca^{++} uptake into the coronary wall that otherwise would occur within 4 days after intramuscular injection of vitamin D_3 (300,000 IU/kg). **B,** Same observations as in **A** made on the rat renal arteries. Under the present experimental conditions, the relatively high oral doses of diltiazem were well tolerated during 4 days without any discernible negative side effects. Reprinted from Fleckenstein et al.[29]

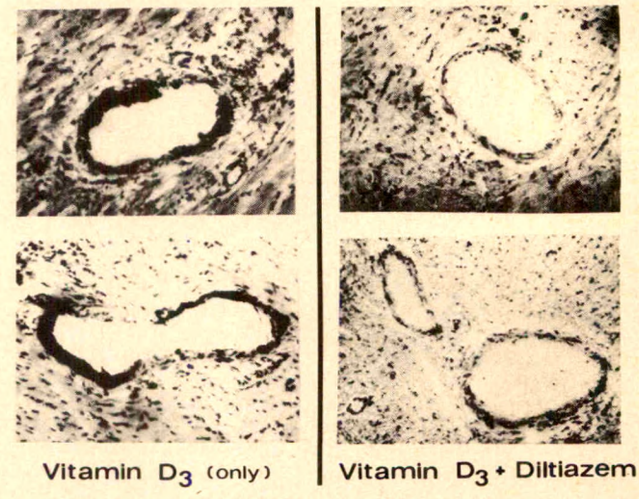

FIGURE 11. The 2 histological sections, **left,** show excessive Ca^{++} accumulation in the wall of rat coronary artery branches 4 days after 1 intramuscular injection of 300,000 IU vitamin D_3/kg body weight. Tissue calcinosis is visualized in the form of black areas with von Kossa's histochemical staining technique.[34] In contrast, calcinosis is totally absent in the 2 sections, **right,** originating from rats that had received diltiazem (2 × 500 mg/kg orally with a stomach tube) for 4 consecutive days after 1 intramuscular injection of 300,000 IU vitamin D_3/kg body weight. This treatment completely neutralizes the vitamin D_3 effects (see also Figure 10A). Reprinted from Fleckenstein et al.[29]

stain for tissue Ca^{++}.[34] Figure 11 shows some typical results. In the absence of diltiazem, the coronary arterial walls responded to vitamin D_3 with massive calcification and severe structural damage. In contrast, by simultaneous administration of diltiazem, the formation of black Ca^{++} deposits in the coronary smooth musculature could be totally prevented.

Under the influence of vitamin D_3 (in the given dose), the plasma Ca^{++} concentration increased by roughly 50% whether diltiazem had been given or not; however, with diltiazem the coronary wall tissue was shielded from excessive Ca^{++} uptake. This can be realized even by simple stereomicroscopic inspection of the coronary arteries in situ (Fig. 12).

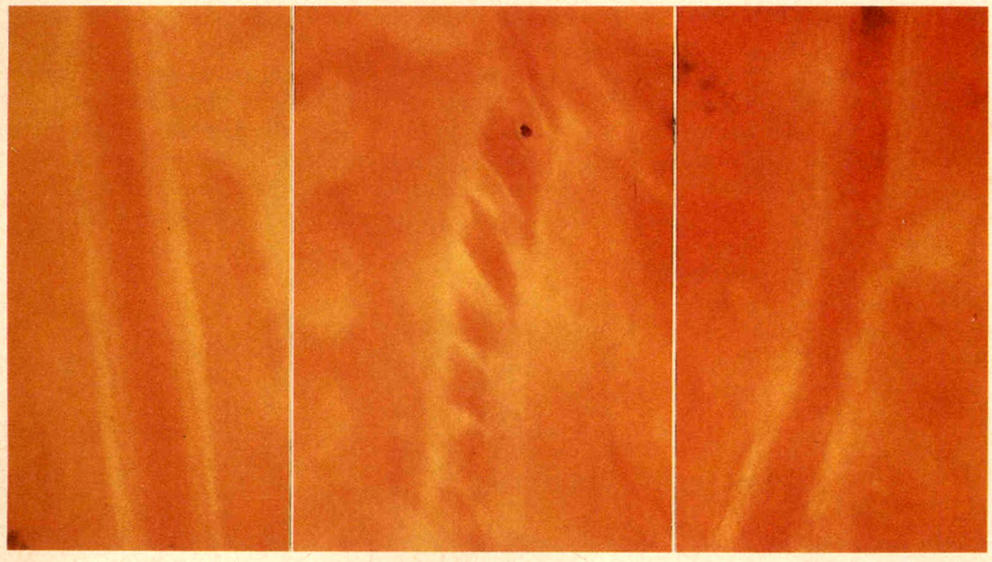

FIGURE 12. A massive calcinosis of the coronary stem arteries is produced in normotensive rats by the combination of 1 intramuscular injection of vitamin D_3 (300,000 IU/kg) with daily oral doses of nicotine (2 × 25 mg /kg) for 4 consecutive days. In these cases, the calcification of the coronary wall tissue is so spectacular that macroscopically discernible spiral plaques appear regularly within 4 days. However, with diltiazem (2 × 50 mg/kg) subcutaneously for 4 days, excessive Ca^{++} uptake and serious damage are prevented.

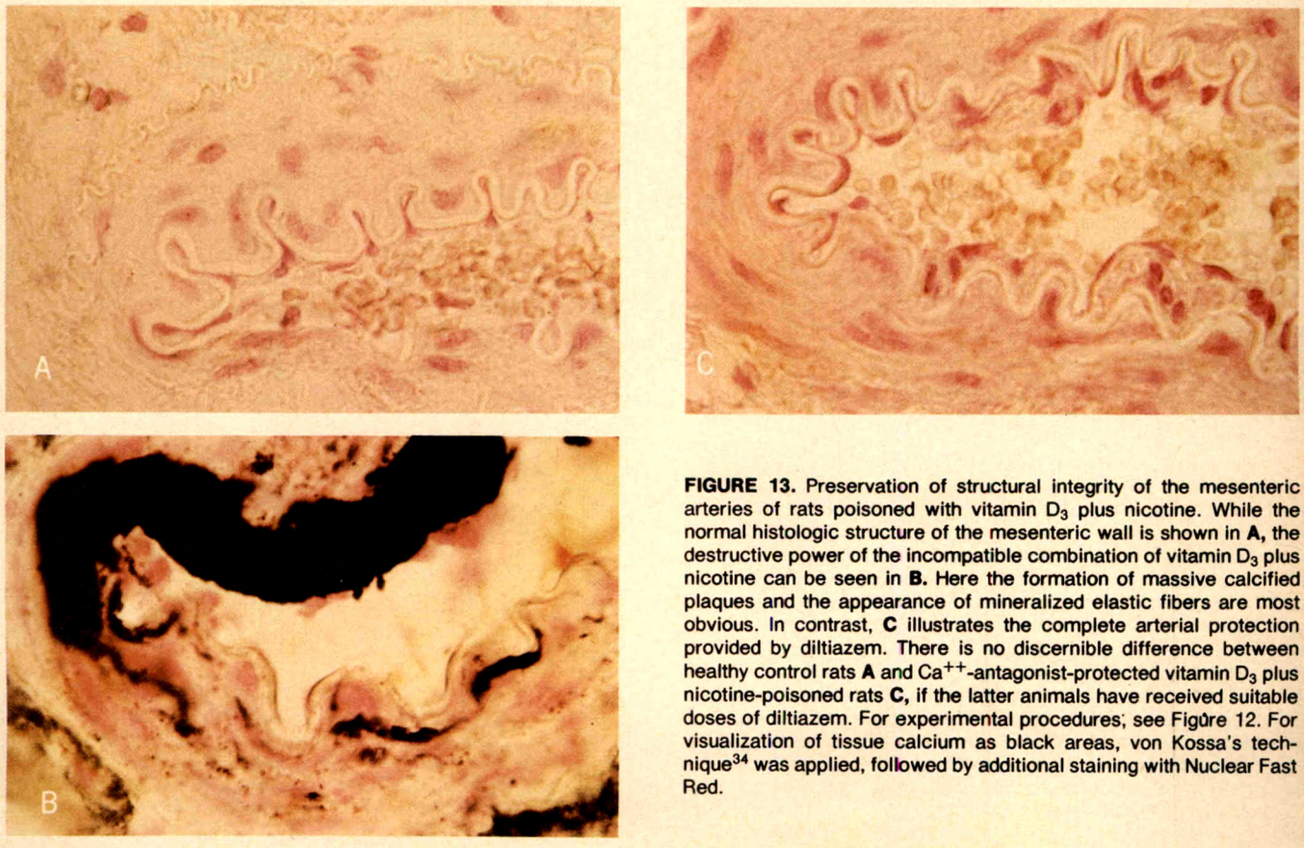

FIGURE 13. Preservation of structural integrity of the mesenteric arteries of rats poisoned with vitamin D_3 plus nicotine. While the normal histologic structure of the mesenteric wall is shown in **A,** the destructive power of the incompatible combination of vitamin D_3 plus nicotine can be seen in **B.** Here the formation of massive calcified plaques and the appearance of mineralized elastic fibers are most obvious. In contrast, **C** illustrates the complete arterial protection provided by diltiazem. There is no discernible difference between healthy control rats **A** and Ca^{++}-antagonist-protected vitamin D_3 plus nicotine-poisoned rats **C,** if the latter animals have received suitable doses of diltiazem. For experimental procedures; see Figure 12. For visualization of tissue calcium as black areas, von Kossa's technique[34] was applied, followed by additional staining with Nuclear Fast Red.

The anticalcinotic action of diltiazem is not restricted to the coronary vasculature, because the aortic, cerebral, mesenteric and renal (Fig. 10B) arterial walls were similarly protected by prophylactic diltiazem treatment. Figure 13B shows the typical media calcification of the mesenteric artery of a rat under the influence of vitamin D_3 and nicotine. Apart from calcified elastic fibers, the most spectacular change consisted of the development of massive calcific plaques. With diltiazem, however, the structural integrity of the mesenteric wall of the vitamin D_3-plus-nicotine–treated rats was fully preserved (Fig. 13C). In a series of more than 40 diltiazem-protected rats, in none did an appreciable aberration from the normal structure of the mesenteric wall (Fig. 13A) occur. Table I summarizes our studies on rats, in which the anticalcinotic efficacy of various Ca^{++} antagonists has been established under different experimental conditions.

In this context we emphasize that vitamin D_3-poisoned rats not only suffer from excessive Ca^{++} uptake into the arterial walls, but also accumulate cytotoxic amounts of Ca^{++} elsewhere,[37] e.g., in heart, kidney, intestinal smooth muscle (Figs. 14A and 15A). Again, suitable Ca^{++} antagonists (for instance, verapamil and diltiazem) provided a highly efficient anticalcinotic tissue protection. Figures 14B and 15B demonstrate the preservation of renal and intestinal integrity with diltiazem. Corresponding analytical data on the prevention of renal and intestinal Ca^{++} overload by diltiazem are shown in Figure 16.

In summary, Ca^{++} antagonists have been used to date in vascular therapy for *acute* functional vasodilation and spasmolytic purposes. The primary aim has been to improve, as quickly as possible, the blood supply to the heart and other organs by removal of purely functional obstacles (spasms) or by enlargement of collaterals and partially obliterated arteriosclerotic vessels. However, in the present context there is a question of much greater medical significance. Are these drugs also capable of exerting long-term anticalcinotic and antiarteriosclerotic effects, and can they,

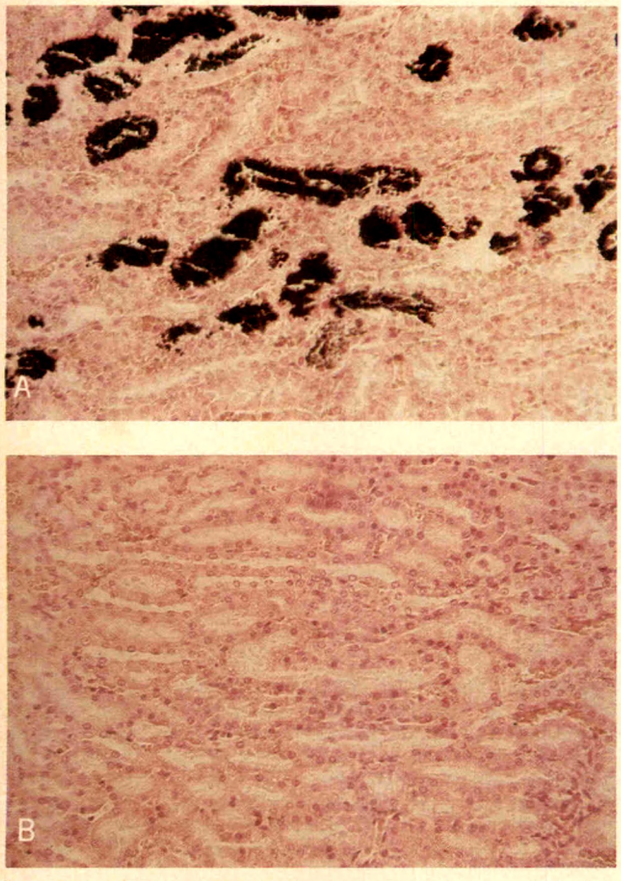

FIGURE 14. A, Severe renal calcification and tissue damage produced by combined administration of vitamin D_3 and nicotine, according to the procedure described in Figure 12. **B,** Complete anticalcinotic renal protection with diltiazem (dosage as in Figure 12). For visualization of tissue calcium as black areas, von Kossa's technique[34] was applied, followed by additional staining with Nuclear Fast Red.

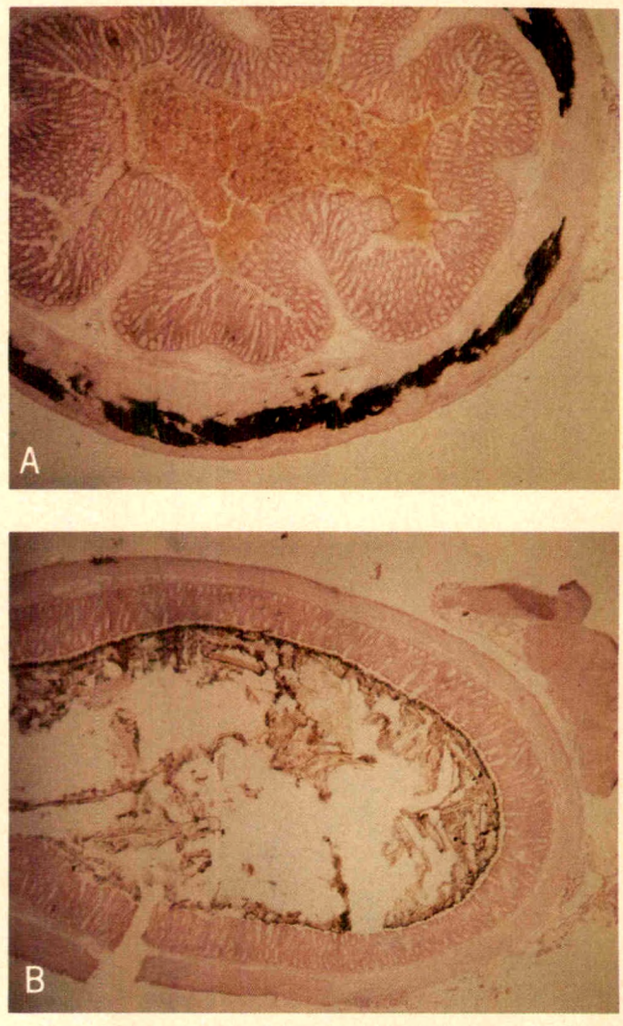

FIGURE 15. A, Calcification of intestinal smooth muscle produced by combined administration of vitamin D_3 plus nicotine according to the procedure described in Figures 12 to 14. **B,** Complete protection with diltiazem of intestinal smooth musculature against calcific necrotization (dosage as in Fig. 12). For visualization of tissue calcium as black areas, von Kossa's technique[34] was applied, followed by additional staining with Nuclear Fast Red.

TABLE I Types of Arterial Calcinosis Studied in Experiments on Rats

Type of Arterial Calcinosis	Effective Ca^{++} Antagonists Examined	References
Intoxication with dihydrotachysterol (AT 10) or vitamin D_3	Verapamil, diltiazem	1,3,28–30,32,33
Hereditary spontaneous hypertension	Nifedipine, nisoldipine, nitrendipine, nimodipine, verapamil	1,3,12,27–30
Advanced age	Verapamil	28,29
Alloxan diabetes	Verapamil	1,3,28,29
Chronic oral administration of nicotine*	Nifedipine, verapamil, diltiazem	28
Combined administration of vitamin D_3* plus nicotine	Diltiazem, verapamil	28

* See also the recent abstracts of our research group: Naunyn-Schmiedebergs Arch Path Pharmacol 1984;325:R43, Pflügers Arch ges Physiol 1984;400:R25 and J Mol Cell Cardiol 1984;16:suppl 2:64.

in this way, counteract vascular damage at its roots? This would mean that the Ca^{++} antagonists not only afford symptomatic improvement, but also interfere with the fundamental pathogenic process of excessive arterial Ca^{++} engulfment and its destructive consequences.

Spontaneous hypertension in rats represents a particularly interesting model in which the complexity of the arterial protection by Ca^{++} antagonists can be visualized. Obviously, *chronic hypertension* maintained over 18 months is closely linked with the development of severe arteriosclerotic lesions in systemic arteries (particularly the mesenteric artery). Suitable Ca^{++} antagonists prevent both essential hypertension and associated arterial damage.

However, progressive arterial Ca^{++} overload also occurs in aging normotensive rats, and can be experimentally enhanced at constant normal blood pressure by the well-known "coronary risk factors" (high doses of nicotine, dihydrotachysterol, vitamin D_3 or alloxan-induced diabetes). Ca^{++} antagonists interfere even in these cases with destructive Ca^{++} overload of the arterial walls and other organs. In other words, vascular protection by Ca^{++} antagonists seems to be exerted in a dual way, namely, by a superposition of antihypertensive and anticalcinotic effects.

All these experimental observations encourage a broader use of Ca^{++} antagonists in human antihypertensive therapy, particularly at an advanced age as proposed by Bühler[35] and Laragh.[36] Although clinical evidence of antiarteriosclerotic properties for Ca^{++} antagonists is still missing, further long-term treatment of hypertension with Ca^{++} antagonists will certainly create favorable conditions for parallel studies on human arteriosclerosis.

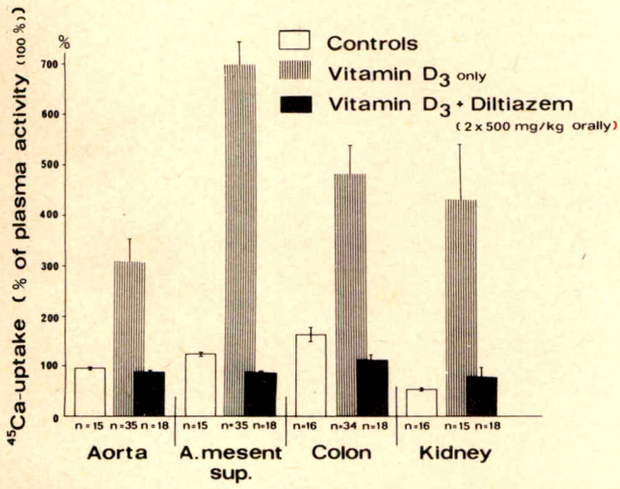

FIGURE 16. Inhibition of vitamin D_3-stimulated net radio-labeled calcium uptake into the walls of rat aorta and mesenteric artery by treatment with oral diltiazem. Simultaneously with inhibition of arterial Ca-45 incorporation, the vitamin D_3-induced calcinosis of renal cortex and colon (flexura dextra) is totally prevented. The specimens of myocardium, aorta, mesenteric artery, kidney and colon analyzed for Ca-45 uptake originated from the same animals. Experimental procedure as in Figure 10. Determination of the net Ca-45 uptake into the different organs was carried out 6 hours after intraperitoneal injection of 10 μCi Ca-45/kg body weight. Reprinted from Fleckenstein.[1]

Experimental Chronic Cerebrovascular Spasm in the Monkey: An Assessment of the Functional Changes in the Cerebral Arteries and Their Protection by Diltiazem

JOHN A. BEVAN, MD, ROSEMARY D. BEVAN, MD, and JOHN G. FRAZEE, MD

The structure and function of cerebral arteries obtained from a monkey model of chronic cerebral vascular spasm 5 days after hemorrhage have been examined. Narrowing of the larger cerebral arteries demonstrated by angiography at all sites of measurement seems to be due primarily to an increased wall rigidity associated with cellular damage, the resultant inflammatory response and large, long-lasting spontaneous increases in muscle tone. Changes in agonist sensitivity were extremely variable. The reduction of contractility of the vessel wall to a mean of 30% of control diminished the consequence of any changes in active tone characteristics. Neurogenic control on the side of the lesion was remarkably depressed.

When treated with diltiazem, beginning 1 day before induction of hemorrhage and continuing to the time of sacrifice, arterial diameter was reduced at only 1 of the 6 standard sites of measurement and then by only a small amount. Neurologic effects invariably seen in the untreated monkeys were prevented by diltiazem. Many of the changes in the artery wall, including structural alterations, were diminished by the drug. Abnormal spontaneous myogenic tone was present but was less in the diltiazem-treated group; however, nerve damage and its functional consequences were not prevented. It is concluded that diltiazem, presumably by preventing the accumulation of intracellular calcium within the cell, prevents the initial events in the evolution of chronic cerebrovasospasm or narrowing. This is probably achieved by a diminishing of the direct vasoconstrictor effects and the toxicity of putative spasmogens released from blood clots, nerves and the brain on the vascular smooth muscle, thus interrupting the sequence leading to pathologic change.

(Am J Cardiol 1985;56:15H–20H)

We studied the chronic cerebrovascular vasospasm that developed after subarachnoid hemorrhage was induced in monkeys (*Macaca nemistrina*). This model resembles human disease because the vasospasm shows a prolonged course extending over several weeks, is diffuse and mainly unilateral, is invariably associated with a neurologic defect[1] and, in the established state, is minimally responsive to vasodilators.[2]

We attempted to test as many of the proposed causes of cerebral vasospasm (some of which are not mutually exclusive) as possible in this study. They include (1) active vascular smooth muscle contraction due to the localized and persistent effects of vasoconstrictor substances released from tissues and blood clots,[3–10] (2) vessel hyperreactivity associated with denervation hypersensitivity, resulting from the now well-established damage to perivascular sympathetic nerves[11–13] and (3) structural changes associated with thickening and decreased distensibility of the artery wall; these changes are presumed to arise from damage caused by arterial rupture and from toxic effects of high concentrations of a variety of vasoactive substances.[14–17]

There are other possible factors that might contribute to the overall narrowing that have not been formally proposed as causes of vasospasm. They include (1) overactivity of sympathetic adrenergic vasoconstrictor nerves; the large cerebral arteries are surrounded by a dense adrenergic axonal plexus and although the physiologic response to their activity is usually considered poor, its influence may be exaggerated by other associated changes,[18] (2) decreased activity of the vasodilator innervation; present evidence suggests that these nerves probably release both acetylcholine and vasoactive intestinal polypeptide, but the physiologic role of this neural system is not understood,[19,20] (3)

loss of vascular endothelium; it is probable that the endothelium in cerebral arteries, like that in other blood vessels, releases relaxing factors[21] and endothelial-induced vascular relaxation is sensitive to even low levels of trauma and (4) an exaggerated cerebrovascular smooth muscle response to stretch; a myogenic response to wall stretch is a physiologic characteristic of middle and smaller cerebral arteries.

The technique of causing subarachnoid hemorrhage in the monkey was previously described.[1] Under anesthesia, a 0.4-mm needle with a percutaneous suture is placed through the intracranial part of the internal carotid artery and removed 24 hours later. Control measurements of arterial pressure from arterial puncture are made, and angiography and neurologic examination are performed before needle removal and also on the fifth or sixth day, immediately before the animal is killed. The animal is then bled and the brain is removed and placed in a bath of Krebs bicarbonate solution of the following composition in m*M*: sodium, 144.23; potassium, 4.9; calcium, 1.6; magnesium, 1.2; chloride, 126.7; HCO_3, 25; SO_4^{2-}, 1.19; glucose, 11.1; and ethylenediaminetetraacetic acid, 0.024, equilibrated with 95% O_2-5% CO_2. The circle of Willis and its main branches are dissected free, and corresponding segments from the 2 sides are examined and compared for structural and functional change.

In this study, the following parameters were measured: passive length-tension relation, active wall tension response to electrical field stimulation of vasoconstrictor and vasodilator nerves, responsiveness and sensitivity to various agonists (both constrictor and dilator) and vessel dimensions (internal diameter and wall thickness). Morphologic measurements included light and electron microscopy and catecholamine histofluorescence. In addition, neuronal uptake of tritium-labeled norepinephrine and choline acetyltransferase activity of the arterial wall were determined.

We also investigated the possible protective effects of diltiazem, a calcium-channel blocker. Diltiazem is a benzothiazepin derivative and is thus in a different chemical class from other drugs with similar action, such as nifedipine and nimodipine, which are dihydropyridines, and verapamil, which is related to papaverine. In an in vitro study of rabbit arteries, diltiazem was found to influence cerebrovascular tone mediated through potential-sensitive as well as receptor-operated channels. Higher concentrations were needed to inhibit the myogenic response in these arteries, which probably involves different calcium-entry mechanisms and contributes to cerebrovascular autoregulation.[22]

It seemed reasonable to us when planning these experiments that many of the causes of vasospasm that have been proposed might be antagonized by diltiazem. The initial action of endogenously released substances, which in high concentrations might lead to cellular damage and chronic spastic state, probably involves calcium entry into vascular smooth muscle cells. A partial list of possible spasmogens, proposed mainly on the basis of short-term animal experiments, includes blood and blood products, hemoglobin, histamine, potassium, norepinephrine, prostaglandins and serotonin. Whether the action of most of these substances on monkey cerebral vessels is diltiazem-sensitive has not been established.

Our primary objective was to test the possibility that an early causal step in vasospasm involves calcium entry into the smooth muscle cell and that this step might be antagonized by diltiazem. Monkeys were pretreated with diltiazem, 25 mg/kg 2 times a day, a dose that does not affect arterial pressure in the monkey. We realize that this regimen is not clinically relevant, particularly in an emergency setting when diltiazem could only be administered after the hemorrhage had occurred. However, our main objective was to investigate the potential for drug protection.

We previously reported that diltiazem markedly ameliorates the arterial narrowing measured at 6 standard sites on the angiogram.[23] Without treatment, the mean "most constricted" site in the series was 22% of the prehemorrhagic diameter. After diltiazem, this value was 84%—a difference that was very significant ($p < 0.001$). The most constricted site is probably the one of greatest clinical significance. Although there was still significant narrowing at this site after diltiazem ($p < 0.01$), the reduction in diameter was relatively small. At only 1 standard position of measurement in the diltiazem-treated group (the distal site on the middle cerebral artery) was the diameter of the lesion side less than the preinsult diameter ($p < 0.05$). In the diltiazem-treated group, no changes were found in any animal on neurologic examination; in contrast, consistent neurologic abnormalities were found in the untreated group.

Functional Changes in the Cerebral Arteries Associated with Chronic Cerebral Vasospasm

The most consistent change in the larger cerebral arteries, and the one we feel contributed most to the luminal narrowing, was an increase in vessel wall rigidity, specifically an increased resistance to passive distension (Fig. 1). In most arterial segments, the passive tension-length curve was shifted to the left after hemorrhage on the lesion side compared with the contralateral side. The mean percentage increase in wall tension over the "physiologic range of stress" based upon the Laplace transformation was about 450%. Although arterial wall thickness was minimally and inconsistently increased, it was insufficient to account for the increase in wall rigidity.

Spontaneous excursions of tone were seen in large and small arteries, including a pial artery of about 150μm outside diameter in the distal middle cerebral artery bed, especially on the lesion side. Tone development was large, often approximating the maximal level that the artery could attain, and frequently lasted more than 1 hour. It was dependent on calcium entry into the cell, presumably into vascular smooth cells, from the extracellular space. The capacity of the arterial segments to develop an increase in wall tension in response to a variety of agents was very markedly reduced on the lesion side—on average, to about 30%

of the contralateral side. The most likely explanation for this was damage to the smooth muscle cells. The greatest reduction in contractility in vitro was associated with the greatest arterial narrowing found on angiography. This relation might imply that spasm/narrowing occurred in those vessels that were damaged the most, and that vasopasm is unlikely to be associated with a large component of active vascular tone with or without associated hypersensitivity.

Changes in agonist sensitivity were extremely variable and were often difficult to assess because of the irregular patterns of response and the frequent and prolonged spontaneous increases in tone that were recorded, particularly on the side of the experimental damage. (In vitro sensitivity in the pharmacologic sense can only be satisfactorily measured from a baseline of 0 or at least low-level tone.) There was a trend toward selective increase in sensitivity to serotonin compared with norepinephrine. However, whatever changes in reactivity were present, their functional consequence would be expected to be relatively small, because the ability of the artery wall to contract was very significantly reduced.

Efferent nerve integrity was assessed by biochemical and functional in vitro study. All measurements—the responses to electrical field stimulation, choline acetyltransferase and tritium-labeled norepinephrine neuronal uptake—indicated a dramatic and consistent depression of both constrictor and dilator neuronal activity. We attempted to determine endothelial influences on smooth muscle tone in vitro by measuring the dilator response to acetylcholine after tone had been elevated. Dilation was invariably absent in arteries from both sides—although the arteries invariably relaxed in response to such vasodilators as papaverine and nitrate. The fact that the acetylcholine response is readily eliminated by handling—by such trivial injury as contact between adjacent endothelial surfaces—and was only occasionally and weakly encountered in sham-operated controls precludes a clear-cut association between loss of endothelial-based dilation and subarachnoid hemorrhage. However, the consistent observation of marked structural endothelial damage, which will be discussed, especially in the arteries on the side of experimental hemorrhage, strongly implies that endothelial-based dilation would not occur in vivo.

Structural Changes in the Cerebral Arteries Associated with Chronic Cerebral Vasospasm

In many respects, the structural changes in the wall correlate with the functional changes just described. Ring arterial segments were taken from comparable sites on the terminal part of the internal carotid artery and the middle and anterior communicating cerebral arteries. In addition, whole-mount segments from those arteries close to the base of the brain were processed for specific catecholamine fluorescence microscopy. In vessels taken from nontreated monkeys, clots were found adhering to the artery wall, particularly the anterior segment. The subjacent arterial wall was grossly abnormal; it was edematous with inflammatory cell infiltration, particularly of the adventitia and around the perivascular nerves, mainly by macrophages and fibroblasts. Almost invariably, there was separation of the internal elastic lamina and degenerative changes in the tunica media with vacuolation of the smooth muscle cells. There was also consistent separation of the tunica intima and subintimal tissues with subendothelial accumulation of fluid and cellular debris. Changes were relatively minor in the diltiazem-treated group; marked degeneration was not seen in the smooth muscle cells, although some vacuolation was encountered.

Diltiazem did not prevent loss of specific catecholamine fluorescence in adrenergic nerves on the lesion side. Large, intensely fluorescent nerve bundles were often seen proximal to the site of puncture. Beyond the area of damage, fluorescent nerves were infrequently seen; fluorescence intensity was markedly diminished, although changes were patchy. Using elec-

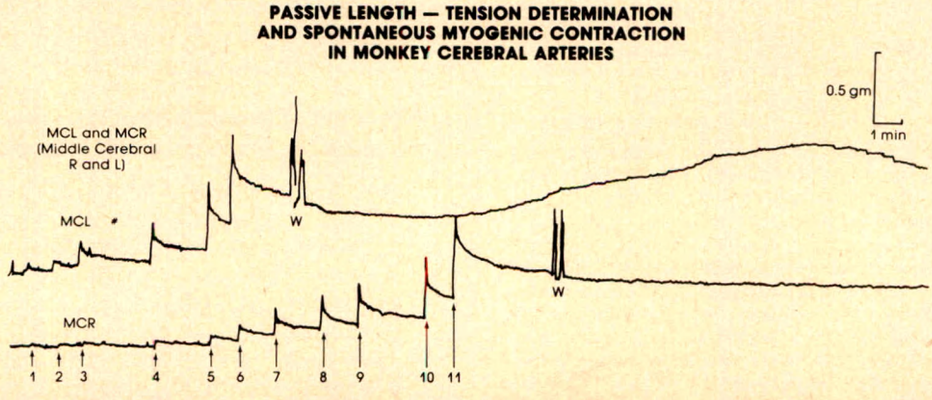

FIGURE 1. Experimental records from in vitro study of segments of middle cerebral arteries in the monkey. Five days previously, the monkeys experienced subarachnoid hemorrhage after experimental puncture of the left intracranial internal carotid artery. The record shows exaggerated increase in tension after standard increments of wall stretch in the left compared with the right side. It also shows a small, short, spontaneous increase in wall tension on the lesion but not on the contralateral side. These 2 phenomena represent the major consistent changes in the large cerebral arteries, which may be the major contributors to arterial narrowing. W = experimental artifact when physiologic saline in tissue bath was changed.

tron microscopy, we observed mixed perivascular nerve bundles that showed degenerative change.

These alterations are consistent with the increased rigidity of the arterial wall, the loss of contractility and the marked diminution of neurogenic reactivity that have already been described. We can only surmise that the abnormal myotonicity is related to minimal levels of damage of the vascular smooth muscle cells.

Assessment of the Contribution of Various Arterial Changes to Luminal Narrowing

It is quite clear that the extreme arterial narrowing called spasm could be the consequence of one or more of the changes already described. In this study, the arteries were only examined on the fifth or sixth day after hemorrhage. Because different arterial attributes were assessed in anatomically separate but adjacent segments, only a fragmentary idea of the changes that take place in these vessels can be formed and then only for the day the animal was killed. Any generalization necessitates considerable extrapolation.

The increase in wall stiffness, the hypersensitivity to agonists, the loss of dilator nerve influence and possibly the absence of endothelial-derived dilation should all be considered as possible causes of arterial narrowing. In addition, there may be changes that we have not measured—for example, those that only occur in situ—in which local constrictor influences could be at work. Thus we cannot, on the basis of these experiments, reach any definitive conclusion with respect to the dominant cause and the relative importance of any contributing factors. However, certain inferences can be made from the mean changes in wall

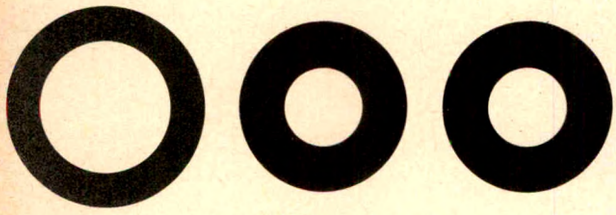

FIGURE 2. Diagrammatic representation of cross section of artery with a wall:lumen ratio of 1:4 is shown, **left. Middle** shows the estimated consequence of a mean change in wall rigidity measured in the monkey series at a blood pressure equivalent to that experienced in the artery at the base of the brain in vivo. A 10% increase in wall mass was assumed. **Right** shows a vessel with changes similar to those depicted in the middle, but also showing the consequence of denervation hypersensitivity (× 3 increase) and a tone increase in response to vasoactive substances equivalent to 30% of maximal contraction (EC_{30}). All of these effects are attenuated by a simultaneous 70% loss of contractility. These mean alterations were found in the large cerebral arteries of the monkeys in this study. It is assumed that vascular smooth muscle cells shorten maximally by 30% of their length and that constriction occurs without changes in wall mass.

elasticity found in the control untreated monkey series, in conjunction with the protective effect of diltiazem. The *mean* change in elasticity alone would be expected to cause a reduction of internal arterial diameter of 40%. If such a narrowing occurred consistently throughout the resistance vessels of the arterial tree, flow would be reduced by about 80%. In particular segments, the increased rigidity would be responsible for an even greater narrowing. The diameter of the most constricted arterial segment in this series was narrowed by approximately 80%. In Figure 2 the changes in an artery associated with this change in elasticity, in which wall mass also increased by 10%, are shown. We found that abnormal myogenic tone was also marked; however, its consequence on wall tension is difficult to assess because the myogenic influence would be decreased by associated reductions in contractility. However, in most cases, we feel abnormal myogenic tone would have a significant influence on arterial diameter.

Figure 2 also shows the additional changes expected from the action of unspecified vasoactive substances that increase smooth muscle tone to an equivalent of 30% of its maximal capacity to contract. The effects of a hypersensitivity factor of × 3, which is probably greater than that associated with denervation in a vessel in which contractility is diminished by 70%, are included. If these approximations have any relevance at all to the intact state, it can be seen that the contribution of the alteration in elasticity is most influential in diminishing luminal diameter. It is assumed that these changes in wall tone take place without significant alteration in wall volume.

In the small pial vessels that we have studied —which are of the order of 150μ outside diameter—the most dominant change was an abnormal myogenic tone. However, because of the irregular and apparently random pattern, such changes were hard to quantitate and relate to the intact circulation. Their magnitude, however, does suggest that they would be of considerable consequence.

We can only speculate that the greater the distance from the initial injury and hemorrhage site—that is, the more distal along the arterial bed—the less important would be passive wall changes and, probably up to a point, the greater the influence of any active, particularly spontaneous, changes in tone.

Effect of Diltiazem on Structural and Functional Changes in Chronic Cerebral Vascular Spasm

Pretreatment with diltiazem greatly attenuated the arterial narrowing as assessed by angiography and prevented the associated neurologic defect.[23] Essentially, changes in cerebral arterial wall elasticity as assessed by the passive length-tension relation were averted. In several monkeys, these curves, which were derived from corresponding segments of the 2 sides, could virtually be superimposed. Neither change in wall thickness nor trend toward an increase was detected. The effect of the drug on these parameters was clear-cut and convincing. However, spontaneous changes in

myogenic activity were recorded that were very much greater on the lesion side compared with the opposite side and, in absolute terms, were sizable. Arterial wall contractility was to a large measure preserved in the diltiazem-treated group. Thus, the spontaneous changes in tone—if related to the capacity of the wall to contract—were diminished in the diltiazem-treated animals. It should be kept in mind that by the time arterial segments were examined in vitro, they had been removed from the animal for several hours and constantly bathed in Krebs bicarbonate saline solution. It seems likely that diltiazem present in the artery wall upon removal would have been washed out before the in vitro study. Because this myogenic activity was depressed by diltiazem added to the tissue bath, it is probable that it would be inhibited in vivo. Nevertheless, the exact role of this phenomenon in vasospasm is enigmatic. It is not the same as "physiologic" stretch-dependent tone, which is readily lost on handling and which shows a direct causal relation to wall tension.[24]

Changes in sensitivity to agonists did occur in the vessels from the diltiazem-treated monkeys and were extremely variable. Useful comparisons with the untreated monkey series could not be satisfactorily made because of this extraordinary variability. Diltiazem did not preserve neuronal function. The various indexes of neural control were all diminished and did not differ from the untreated series.

The structural changes in the artery wall were consistent with findings of the functional study. The fabric of the wall was far better preserved in the diltiazem-treated compared with the control group; however, the efferent nerve terminals were unprotected.

Evolution of Chronic Cerebral Vascular Spasm

We can only speculate regarding the series of events that culminates in the arterial change that we found on the fifth day of hemorrhage in this monkey model, when vasospasm seemed to be maximal (Table I). Unquestionably, during the hours just after hemorrhage, the cerebral arteries, particularly those at the base of the brain, are surrounded by many putative spasmogens. Their effect on vascular tone would depend almost exclusively on promoting the entry of calcium into the cytoplasm of the vascular smooth muscle cells from the extracellular space. The vasoactivity of most of these substances has been shown in acute in vivo and in vitro studies to be effective in causing a contraction of cerebral arteries that is susceptible to 1 calcium-channel blocker or another.[25–33] It seems reasonable, therefore, to conclude that the initial acute vasospasm (not demonstrated as yet in this model, but that would almost certainly occur and that has been consistently seen in other experimental preparations) is due to active vascular smooth muscle contraction resulting from the activity of such extrinsic substances. Actions of individual substances are probably augmented by synergistic effects and also by changes in the vascular smooth muscle cells themselves. The fact that the narrowing that occurs soon after subarachnoid hemorrhage can be reversed by vasodilator drugs[34] is consistent with such a proposition.

TABLE I Experimental Cerebrovascular Spasm (based mainly on studies of effects of experimental subarachnoid hemorrhage in the monkey)

Spasm	Acute (hours)	Chronic (days)
Cause	Spasmogens released from blood clot, nerves and tissues*	Inflammation of arterial wall, edema, fibrosis
Basis of narrowing	Exaggerated normal active muscle tone*	Increased wall rigidity and active, possibly abnormal, muscle tone*
	Dependent on extracellular calcium	Only active tone dependent on extracellular calcium

Hypothesized differences between 2 phases of vasospasm that occur in the monkey subsequent to experimental subarachnoid hemorrhage. We presume that the second vasospasm follows from the first.

* Possible sites of the protective action of diltiazem, leading to reduction in arterial narrowing.

This early period of true vasospasm presumably merges into a second phase when the changes in the arterial wall resulting from damage become prominent. These changes are probably caused by the high concentrations of vasoactive substances released from many sources, including nerves,[15,35] clots and possibly the brain, and by the reaction of the vascular wall to the ensuing damage, the consequences of which become progressively important. Thus, passive wall changes might be expected to dominate more and more with time. Once these latter processes are established, the resultant narrowing would not be expected to be influenced by vasodilator drugs.[34] Such an explanation is consistent with the biphasic time course of the disease[36] and with the slowly progressive and long-lasting phase of the clinical condition. This theory is also consistent with the well-established resistance of clinical vasospasm to therapeutic manipulation. The gradually progressive dominance of the passive changes associated with rigidity and fibrosis reflects what is seen at autopsy when cerebral arteries show perivascular medial and subendothelial fibrosis and other signs of resolved inflammatory reaction.[16]

We can only speculate that diltiazem is protective because it antagonizes the entry of calcium through channels involved in the physiologic control of vascular smooth muscle tone—potential-sensitive and receptor-operated channels.[37] This entry would be initiated by the vasoactive material present around the artery wall. Further, diltiazem might owe some of its action to its cellular protective potential. Our study of arterial wall change in experimental subarachnoid hemorrhage and the protective effect of diltiazem may help to explain the significant therapeutic effect of nimodipine in some patients with subarachnoid hemorrhage.[38] This latter study was limited in that it was restricted to neurologically normal patients and the severity of the vasospasm was not always assessed. Nevertheless, the finding is of major clinical interest.

Hemodynamic Effects of Calcium Entry–Blocking Agents in Normal and Hypertensive Rats and Man

EDWARD D. FROHLICH, MD

To be considered ideal for the treatment of hypertension, a class of drugs should produce a maintained reduction of arterial pressure primarily through a fall in total peripheral resistance that is at least uniformly distributed through the organ circulations of the target organs of hypertensive vascular disease. Such drugs should be useful as monotherapeutic agents, should not expand the extracellular fluid compartment, should not reflexively stimulate the heart and vessels, should reverse the structural changes in the target organs without compromising function and, of course, should be relatively free of adverse effects. As a heterogeneous class of agents, the calcium entry–blocking drugs fulfill most of these criteria, although preliminary studies suggest that their effects on organ vascular resistances and on structural cardiovascular changes are highly variable. Thus, further vigorous investigation of these new agents is highly recommended.

(Am J Cardiol 1985;56:21H–27H)

The calcium entry–blocking drugs have been widely used in the United States and throughout the world for a number of years for the treatment of patients with ischemic heart disease. Although they have been used over the past decade for the treatment of hypertension elsewhere in the world, they have not yet been approved for this indication by the U.S. Food and Drug Administration. This should stimulate a feeling of déjà vu in physicians who have been in practice during the past 10 to 15 years; it is reminiscent of the story of the β-adrenergic receptor–blocking drugs. A similar long period elapsed between the time they were used worldwide for the treatment of hypertension and when they were approved in the U.S. I have no doubt, however, that the calcium entry–blocking agents are being used as antihypertensive drugs in the U.S. today—presumably for those patients with coexisting ischemic heart disease and hypertension. As is well known, hypotension is the most consistent side effect shared by most of these compounds in patients who have been treated for coronary artery disease.

Hemodynamic Considerations

The hemodynamic hallmark of hypertension, and particularly essential hypertension, is an increased total peripheral resistance that seems to be uniformly distributed throughout all the vascular territories.[1,2] As the left ventricular (LV) afterload (i.e., the rising arterial pressure and total peripheral resistance) increases, the heart adapts by the development of a concentric form of LV hypertrophy.[3–5] Associated with this process is an increased myocardial oxygen consumption that is secondary to 2 factors: one is obviously the increased arterial pressure (in this instance, the systolic pressure); the other is the increased chamber diameter (i.e., the cardiac enlargement) that follows at an equal rate with the ever-increasing afterload.[1–8] Associated with the adaptive structural changes by the heart is the structural change of arteriolar thickening,[9] which is also associated with acceleration of an independent but closely interrelated process, atherosclerosis.[10,11]

In addition to these pathophysiologic considerations related to the progression of hypertensive cardiovascular disease, other physiologic changes are associated with antihypertensive therapy.[12,13] For example, we know that as most drugs reduce arterial pressure, intravascular (plasma) volume expands. There are some agents that are notable exceptions to this rule: diuretics (for obvious reasons), β-adrenergic receptor–blocking drugs, probably the angiotensin converting enzyme inhibitors and, most likely, the calcium entry–blocking drugs. This failure to expand intravascular volume is in contrast to the other classes of antihypertensive drugs (e.g., direct-acting vascular smooth muscle relaxants and adrenergic inhibitors)

TABLE I The Ideal Antihypertensive

An ideal antihypertensive agent should reduce arterial pressure:
- by decreasing total peripheral resistance
- through uniform reduction of organ vascular resistances
- without
  - retaining extracellular fluid
  - reflexively stimulating the heart
- with regression of structural changes that do not impair
  - organ function
  - systemic performance

that must be used with diuretics. The diuretics prevent volume expansion and development of the so-called phenomenon of "pseudotolerance".[14,15] Even those agents that may not be associated with fluid volume retention will show enhanced effectiveness if prescribed together with a diuretic.[16] These observations explain the traditional first 2 steps of antihypertensive therapy: diuretics, followed by adrenergic inhibitors.[17–19] They also explain why the β blockers, angiotensin converting enzyme inhibitors and calcium entry–blockers have been used as first-step monotherapeutic agents for the treatment of hypertension.[20]

A second important factor that may be related to antihypertensive therapy is reflex cardiac stimulation, which occurs with those antihypertensive drugs that do not inhibit adrenergic input to the cardiovascular system.[12,13] For some as-yet-unexplained reason, this also is not generally associated with the angiotensin converting enzyme inhibitors,[21] angiotensin receptor inhibition[22] or certain calcium entry–blocking drugs.[23–25] This concept is important, because reflex cardiac stimulation will increase myocardial oxygen consumption, aortic flow acceleration and myocardial metabolism, and will thereby aggravate associated cardiac problems (e.g., coronary artery disease, myocardial infarction, congestive heart failure and dissecting aortic aneurysm).[26]

Therefore, an ideal antihypertensive agent should reduce arterial pressure primarily by decreasing total peripheral resistance associated with a relatively uniform decline in the vascular resistances in the major vascular territories of the body. However, this arteriolar dilation should ideally involve the primary target organs of the disease: the brain, heart and kidney. Moreover, this pressure reduction should be accomplished without secondary fluid retention or reflex stimulation of the heart. Further, if there is some regression in the associated hypertrophic structural changes without altering performance or function of the organs or the patient, we truly will have an ideal antihypertensive drug (Table I). The discussion that follows will be concerned with how well the calcium entry–blocking drugs measure up to these criteria.

Calcium Entry–Blocking Drugs

Some of the first studies that provided useful information concerning the antihypertensive and hemodynamic effects of the calcium entry–blocking drugs emanated from Italy. Olivari et al[23] reported data from 27 patients who were treated with nifedipine. After 3 weeks of therapy, the reduced arterial pressure was

TABLE II Antihypertensive Effects of Nifedipine in 27 Patients with Essential Hypertension Treated for 3 Weeks

Index	Control	Treatment
Mean arterial pressure (mm Hg)	140	120*
Heart rate (beats/min)	75	74
Cardiac index (liter/min/m^2)	3.6	4.1*
Stroke index (ml/beat/m^2)	49	55
Total peripheral resistance (dynes s cm^{-5})	1,766	1,281*
Plasma volume (ml)	3,149	3,049
Glomerular filtration rate (ml/min)	81	82
Plasma renin activity (ng/ml/hour)

not accompanied by a faster heart rate, although cardiac output was somewhat greater than pretreatment levels; the pressure reduction, therefore, was due to a fall in total peripheral resistance. In addition, there was no expansion of intravascular (plasma) volume, glomerular filtration rate was preserved and plasma renin activity was unchanged (Table II). Muiesan et al[24] compared the effects of verapamil (80 mg, 3 times a day) with nifedipine (10 mg, 3 times a day). A significant pressure reduction was observed with both agents in both the supine and standing positions, without producing orthostatic hypotension; there was no evidence of an increased heart rate (Table III). They also reported that with prolonged treatment, nifedipine increased circulating norepinephrine levels, although verapamil produced no change in supine and standing norepinephrine levels. In addition they found that plasma renin activity, aldosterone levels and plasma volume remained unchanged with prolonged treatment.

Perhaps these early findings explain why most investigators in Europe and Japan now use these agents as first-step monotherapy for treatment of hypertension, without observing fluid retention or reflex cardiac stimulation.[26–29] Muiesan et al[24] also compared 2 dosage levels of verapamil (80 and 160 mg, 3 times a day) with nifedipine (10 mg, 3 times a day) for a 2-month period (Table IV). At the higher verapamil dosage there was a further fall in pressure, which was unassociated with a faster heart rate. When responses to verapamil were compared with those in patients receiving nifedipine, there were no significant differences in plasma renin activity, although at the higher dosage of verapamil, norepinephrine levels (in the upright posture) seemed to be higher. These findings were substantially similar to a number of later reports from other centers.[25–27]

Safar et al[27] recently reported the immediate hemodynamic effects of diltiazem (0.2 mg/kg) in 11 patients with essential hypertension. After intravenous administration there was a significant fall in mean arterial pressure (from 120 to 109 mm Hg) and total peripheral

resistance (from 2,690 to 2,276 dynes s cm^{-5}/m^2), associated with an insignificant increase in cardiac index (from 3.5 to 3.9 liters/min/m^2) and an unchanged heart rate. In addition, the caliber of the brachial artery was significantly increased.[27] More prolonged hemodynamic effects were not reported.

We have recently been investigating the hemodynamic effects of 2 newer calcium entry–blocking agents, diltiazem and nitrendipine, in 2 genetic forms of hypertension: clinical and experimental. In this report we shall compare our preliminary findings in patients with essential hypertension and in spontaneous hypertensive rats (SHRs) and Wistar-Kyoto normotensive rats (WKYs). SHRs are very similar to patients with essential hypertension[28] and permit an extension of our understanding of the many hemodynamic effects that we are not able to learn about in patients for practical and ethical reasons. By using 15-μm diameter microspheres for our hemodynamic studies in conscious, unanesthetized closed-chest rats, we can determine cardiac output and blood flow in every organ of the body.[30–32]

Methods

In brief, our experiment subjects WKYs and SHRs to a 3-week treatment period in a protocol similar to that which we have reported for most of the antihypertensive drugs that we use, including methyldopa,[33–35] clonidine,[35] hydralazine,[35] angiotensin converting enzyme inhibitors,[36] prazosin,[37] urapidil,[37,38] calcium entry–blocking drugs[39,40] and others.[41] We have therefore developed a standardized bioassay (a long-term hemodynamic assay) for ascertaining the comparative effects of new antihypertensive compounds. At the end of a 3-week treatment period, with the animal under light ether anesthesia, catheters were placed through the femoral artery, into the left ventricle, through the carotid artery and into the femoral vein, and then were exteriorized at the back of the neck. When the animal was fully recovered from this procedure, the microspheres were injected. Using the reference method, we determined cardiac output from the radioactive "envelope" of withdrawn arterial blood[30] and then measured radioactivity in all organs to determine the percentage distribution of cardiac output to each organ.[32] Then, by multiplying the cardiac output by the ratio of radioactive counts in any organ to the total radioactivity injected, we calculated a quantitative representation of blood flow to every organ of the body. Moreover, by recording arterial pressure directly, we were also able to calculate the changes in organ vascular resistances (compared with the WKYs, which were not given the drug). In each study, net organ weights were obtained to learn of possible changes in organ mass with therapy and to determine blood flow and vascular resistance indexes.

Our clinical studies were conducted in patients with essential hypertension. In these studies, systemic and regional hemodynamic effects of diltiazem and nitrendipine were determined using our previously reported hemodynamic methods.[42,43] In brief, all patients came to our laboratory in the morning after an overnight fast and after at least 4 weeks of no antihypertensive therapy. Polyethylene tubing was inserted into a brachial artery and antecubital vein to shoulder level for measurement of pressures, injection of dye or vasoactive agents and withdrawal of arterial blood for inscription of the dye curves. Indocyanine green dye, injected centrally and through the vein, permitted calculation of cardiac output. Renal and splanchnic blood flows were determined by injection of radioiodinated para-aminohippurate and indocyanine green dye, respectively. Hemodynamic indexes were calculated by standard methods. Plasma renin

activity, circulating norepinephrine levels and plasma volume were determined by our previously reported methods.[43] M-mode echocardiography was used to determine structural and functional cardiac changes.[7]

In all studies, rat or man, standard statistical techniques, with Student's *t* test for paired data analysis or the patient as his own control, were used.

Results

Diltiazem: *Rat studies:* When the rats were treated with diltiazem (60 mg/day by gastric tube), no systemic hemodynamic changes were observed in normotensive WKYs; however, it produced a significant fall in arterial pressure, associated with a fall in total peripheral resistance, in the SHRs. These systemic hemodynamic changes were also associated with some slowing of heart rate and reduction in cardiac index, which were not of statistical significance. There were no changes in LV mass or the weight ratio of the left ventricle to total body. We also determined changes in organ hemodynamics in these WKYs and SHRs. In the normotensive WKYs, vascular resistance increased in the skin, lungs, kidneys, splanchnic organs and testes, but decreased in the heart. In contrast, vascular resistance decreased in the brain and the splanchnic organs of the SHRs, but remained unchanged in the other organs (Table V). These findings differed somewhat from our preliminary findings in man with essential hypertension.

Clinical studies: We have obtained preliminary hemodynamic measurements in 7 patients with uncomplicated essential hypertension who first received intravenous diltiazem (0.24 mg/kg in divided doses) and were then treated with the oral formulation for 4 weeks. These 7 patients, whose age averaged 47 years, included 6 men and 1 woman. Following logarithmi-

cally incremental doses (0.06, 0.06 and 0.12 mg/kg, intravenously), arterial pressure progressively fell from 118 to 101 mm Hg within a rather short period. This was associated with a reflexive increase in heart rate, cardiac index and LV ejection rate index, as calculated total peripheral resistance declined (Table VI). When these same patients continued treatment for 4 weeks (60 to 120 mg, 2 times a day), arterial (systolic/diastolic) pressures fell from 165/95 to 149/86 mm Hg after 4 weeks. However, the reflexive increase in heart rate, cardiac index and LV ejection rate was no longer observed, while total peripheral resistance was further reduced (Table VII). Thus, after the immediate reflexive stimulation with intravenous diltiazem, more prolonged therapy evoked either some form of baroreceptor "adaptation" or lesser adrenergic stimulation of the heart.

Nitrendipine: *Rat studies:* This compound is a second generation of nifedipine. We administered the drug (20 mg/kg/day) by gastric tube to WKYs and SHRs; similar to our diltiazem experience (60 mg/kg/day), we obtained the same magnitude of reduction in pressure as we had observed with diltiazem. However, the pressure reduction was observed immediately after as well as with prolonged treatment in both the normotensive WKYs and the SHRs.[39,40] This pressure fall was associated with a significant reduction in total peripheral resistance, without a reflexive increase in cardiac index or heart rate (Table VIII). In addition, and unlike our diltiazem experience, both WKYs and SHRs demonstrated a reduced cardiac mass with 3 weeks of treatment. Thus, although the 2 calcium entry–blocking drugs had similar salutary hemodynamic effects, their effects on cardiac mass were different and were not solely related to a reduction of arterial pressure or reversal of LV hypertrophy.

Unlike diltiazem, the immediate effect of nitrendipine (after intravenous injection) on organ hemodynamics was a significant reduction in brain, heart, renal, adrenal and splanchnic vascular resistances in WKYs whereas in the SHRs there was a significant fall in vascular resistance in the heart, kidneys and adrenal glands, and a rise in cutaneous resistance.[39,40] With prolonged treatment (3 weeks) the hemodynamic changes were different from those we observed with diltiazem. Nitrendipine decreased vascular resistance in WKY skeletal muscle and the splanchnic organs, and reduced vascular resistance in skeletal muscle, heart and kidneys in the SHRs (Table IX). Thus, we must conclude that the hemodynamic effects of the calcium entry–blocking drugs on the various regional circulations differ, depending on the agent studied.

Clinical studies: We also studied the immediate hemodynamic effects of nitrendipine in 12 patients with essential hypertension after a single 20-mg oral dose.[25] This permits comparison with the immediate findings in SHRs and in our other patients after intravenous diltiazem. Only 7 of the 12 patients demonstrated an immediate fall in pressure, which was produced by a decreased total peripheral resistance and was associated with a reflex increase in heart rate, cardiac index and LV ejection rate (Table VIII) that could be related

to an increase in circulating norepinephrine levels (from 310 to 481 pg/ml).

Cardiac mass: These findings with diltiazem and nitrendipine with respect to changes in cardiac mass reflect our present lack of understanding of the mechanisms of action of antihypertensive drugs on myocardial protein synthesis. As indicated, the diuretics have little effect on cardiac mass; the vasodilating agents hydralazine and minoxidil also either have no effect or may even increase cardiac mass despite a profound and beneficial hemodynamic effect on reducing LV afterload.[35,44] In contrast, the angiotensin converting enzyme inhibitors may reduce cardiac mass in hypertensive animals[36,45] and man.[21,46] The centrally acting antihypertensive agents have varying effects: methyldopa reduces cardiac mass in normotensive and hypertensive animals[34,35,47] and in hypertensive patients,[48,49] whereas clonidine, an agent with similar pharmacologic and hemodynamic effects, does not reduce mass until high doses are used that no longer exhibit antihypertensive effects.[35]

The heterogeneous class of calcium entry–blocking agents displays varying effects on cardiac mass, and this may be related to their respective intracellular actions.[50] It is of interest that those agents that reduce cardiac mass only seem to affect protein synthesis in the heart; in each of the foregoing studies the weights of the other organs remained unaffected.[33,35,40] A variety of mechanisms has been offered as explanation for the reduction in cardiac mass; it has been variously attributed to stimulation of the renin-angiotensin system, the adrenergic nervous system or perhaps those factors that inhibit calcium entry.[4,8,40] Tissue culture studies have shown that addition of angiotensin II initiates protein synthesis;[51] and infusion of norepinephrine and other adrenergic agents in subpressor amounts also initiates ventricular hypertrophy.[52,53] It is clear that our understanding of this phenomenon is only beginning. Until we understand the molecular mechanisms involved in protein synthesis—and the fundamental mechanisms that serve to transduce the physiologic signal of pressure overload to the biochemical response of myocardial protein synthesis—this understanding will remain incomplete.

Effects of Diltiazem on Hormonal and Hemodynamic Responses to Lower Body Negative Pressure and Tilt in Patients with Mild to Moderate Systemic Hypertension

PRAMOD K. MOHANTY, MD, JAMES R. SOWERS, MD, CAROLYN McNAMARA, RN, BARBARA WELCH, MS, FRANCES BECK, MS, and MARC D. THAMES, MD

Mean arterial blood pressure, forearm vascular resistance, plasma norepinephrine, plasma renin activity and aldosterone responses to graded lower body negative pressure and tilt at 80° were examined in 10 men with mild to moderate essential hypertension before and after 12 weeks of diltiazem (240 to 360 mg/day) therapy. Diltiazem therapy lowered basal supine systolic and diastolic blood pressures without affecting basal heart rate. Mean arterial blood pressure and forearm vascular resistance were decreased from 114 ± 1.5 to 105 ± 1 mm Hg, $p < 0.01$ and from 29.3 ± 3.5 to 18.9 ± 2.1 units, $p < 0.01$, respectively. Diltiazem therapy had no effect on basal supine levels of norepinephrine, plasma renin activity or aldosterone, nor on the responses of these hormones to lower body negative pressure. Diltiazem did decrease the forearm vascular resistance responses to lower body negative pressure and tilt. Diltiazem abolished an orthostatic increase (10 ± 0.3 mm Hg) in mean arterial blood pressure and this was associated with a greater plasma norepinephrine response to tilt. These results suggest that diltiazem decreases vascular resistance through a reduction in the postjunctional effects of norepinephrine on vascular smooth muscle.

(Am J Cardiol 1985;56:28H–33H)

Diltiazem hydrochloride, a Ca^{++} flux inhibitor, appears to lower blood pressure primarily by reducing peripheral vascular resistance.[1–4] Diltiazem and other Ca^{++} flux inhibitors exert their smooth muscle vasodilatory effects partly through interference with catecholamine-induced vasoconstriction.[5] Norepinephrine increases transmembrane Ca^{++} transport into smooth muscle, through α_1 and α_2 adrenoceptor-modulated opening of slow calcium channels, thereby causing vasoconstriction.[6,7] In addition, Ca^{++} may increase the release of catecholamines from the adrenal medulla[8] and calcium-channel blockers appear to interfere with these processes.[5,9] The effect of calcium-channel blockers on norepinephrine-induced vasconstriction is further evidenced by the observation that diltiazem attenuates the rise in blood pressure associated with norepinephrine infusion.[10,11]

Sympathetic nervous system input into the skeletal muscle vasculature plays an important role in regulating muscle blood flow.[12–15] Sympathetic nervous system input into this vascular bed is modulated by several inhibitory reflexes, including a "low pressure" cardiopulmonary baroreceptor system.[16–19] Low-level lower body negative pressure, through reduction of cardiothoracic blood volume, causes significant activation of sympathetic nervous system outflow, as evidenced by increases in forearm vascular resistance[13–19] and plasma norepinephrine levels.[19] Because low-level lower body negative pressure does not alter arterial blood pressure or heart rate,[3,14,16–19] it is apparent that changes in low pressure cardiopulmonary baroreflex activity can increase peripheral sympathetic activity and vascular resistance. Although augmentation of cardiac baroreflexes has been demonstrated in mild to moderate hypertension,[18,20] it is not known whether therapy with a Ca^{++} flux inhibitor such as diltiazem

TABLE I Mean ± Standard Error of the Mean Systolic and Diastolic Blood Pressure (BP) and Heart Rate Responses to Lower Body Negative Pressure and Tilt (80°) in 10 Men with Mild to Moderate Hypertension Before and After 12 Weeks of Diltiazem Therapy (DT)

Measurement		Baseline	−10 mm	−20 mm	−40 mm	Tilt (80°)
Systolic BP	Pre-DT	145 ± 2.5	140 ± 3	142 ± 3	137 ± 4	147 ± 5
(mm Hg)	Post-DT	136 ± 3*	138 ± 4	139 ± 3	133 ±5	131 ±3*
Diastolic BP	Pre-DT	98 ± 1	93 ± 2	93 ± 2	96 ± 2.5	107 ± 3
(mm Hg)	Post-DT	85 ± 2**	85 ± 2	84 ± 2.5*	87 ± 2.5*	92 ± 2**
Heart rate	Pre-DT	72 ± 3	72 ± 4	71 ± 3	76 ± 3	80 ± 4
(beats/min)	Post-DT	68 ± 2	66 ± 3	66± 3	71 ± 4	82 ± 2

* $p < 0.05$; ** $p < 0.01$ for post-DT versus pre-DT.

has any effect on these augmented cardiac baroreflexes. In the present study we evaluated the effects of diltiazem therapy on hormonal and hemodynamic responses after selective activation of low pressure cardiopulmonary baroreflexes through graded lower body negative pressure and tilt.

Methods

Ten men, aged 33 to 66, with mild to moderate essential hypertension, were studied in the Hypertension Research Laboratory at the McGuire Veterans Administration Medical Center. Mean arterial blood pressure ranged from 95 to 114 mm Hg after all antihypertensive medications had been discontinued for 4 weeks. The patients had no other major medical illnesses such as coronary artery disease, congestive heart failure, renal insufficiency, chronic obstructive lung disease or diabetes mellitus. Studies were conducted before and after 12 weeks of diltiazem therapy at a dosage level of 120 to 180 mg, 2 times a day.

On study days, baseline blood sampling and hemodynamic measurements were initiated with the patients in a supine position and after having a heparin lock placed in a forearm vein of the left arm for 30 minutes. In order to selectively activate low pressure baroreceptors with lower body negative pressure, subjects were positioned in a lower body negative pressure chamber that encased them below the iliac crest. The chamber was sealed and connected to an adjustable vacuum. Graded lower body negative pressure was applied at −10, −20 and −40 mm Hg. Lower body negative pressure was maintained at each consecutive level for 5 minutes at 10-minute intervals. Forearm blood flow was measured in the right arm with a mercury-in-silastic strain gauge plethysmograph and intermittent venous occlusion technique as previously described.[21] Blood pressure was measured in the left arm by an automatic cuff method and recording device (Critikon model 1160). Forearm blood flow was calculated from the rate of increase in forearm volume during venous occlusion expressed as ml/min/100 ml forearm volume. Forearm vascular resistance was then calculated by dividing the mean arterial pressure (diastolic pressure plus one-third of the pulse pressure in mm Hg) by the forearm blood flow.

After the lower body negative pressure studies, the subjects remained supine for 30 minutes; then basal hemodynamic determinations and blood sampling were done. The subjects were then tilted at an 80° angle with the horizon and measurements were repeated after 10 minutes of tilting.

Blood samples (6 ml) were obtained before and after each level of lower body negative pressure, as well as before and after tilt for measurement of plasma catecholamines, plasma renin activity and aldosterone. Samples for catecholamines were collected in prechilled heparinized tubes and plasma was stored at −100° C until assayed. Catecholamines were assayed by high performance liquid chromatography, using electrochemical detection.[22,23] Detection in this system is coulometric and the sensitivity is less than 5 pg for norepinephrine, dopamine and epinephrine. Plasma renin activity was measured by radioimmunoassay for angiotensin I after titration to a pH of 7.4 with phosphate buffer and incubation at 37° C in the presence of angiotensinase inhibitors.[24] Sensitivity of this assay is 0.2 ng/ml/hour and intrassay coefficient of variation is 4%. Aldosterone was measured by radioimmunoassay after extraction and column separation.[24] Sensitivity for this assay is 0.4 ng/dl and the intrassay coefficient of variation is 6%. Statistical differences in levels of plasma catecholamines, plasma renin activity, aldosterone and hemodynamic parameters, as well as responses to lower body negative pressure and tilt before and after diltiazem treatment, were determined by analysis of variance. Multiple regression analysis was used to calculate correlation coefficients between various parameters, and values are significant at $p < 0.05$. Data are presented as mean ± standard error.

Results

Table I shows that diltiazem therapy decreased both resting supine systolic and diastolic blood pressures in these 10 men with mild to moderate hypertension. Mean arterial pressure was decreased ($p < 0.01$) from 114 ± 1.5 to 105 ± 1 mm Hg over the 12-week treatment period. Neither systolic nor diastolic blood pressure changed in response to graded lower body negative pressure (Fig. 1). Before diltiazem therapy, there was an increase in both systolic ($p < 0.05$) and diastolic ($p < 0.01$) blood pressure in association with tilt. After diltiazem therapy, the increase in systolic and diastolic blood pressure with tilt was eliminated. Diltiazem therapy alone had no effect on heart rate. There was no change in heart rate associated with lower body negative pressure before or after diltiazem treatment; however, heart rate increased ($p < 0.05$) with tilting both before and after diltiazem therapy.

Diltiazem therapy was associated with a decrease ($p < 0.01$) in supine basal forearm vascular resistance from 29.3 ± 3.5 to 18.9 ± 2.1 units. The reduction in basal forearm vascular resistance correlated ($r = 0.74$) with the reduction in mean arterial pressure. Forearm vascular resistance was incrementally increased from −10 through −40 mm Hg of lower body negative pressure before diltiazem (Fig. 1). The incremental responses in forearm vascular resistance to lower body negative pressure were markedly decreased ($p < 0.001$) after diltiazem therapy at all levels of graded lower body negative pressure.

There was no change in plasma dopamine, epinephrine or norepinephrine levels in response to lower body negative pressure or tilt. Before diltiazem therapy there was an increase ($p < 0.01$) in plasma norepinephrine from 132 ± 14 ng/ml to 189 ± 15 ng/ml at −10 mm Hg of lower body negative pressure and to 265 ± 55 ng/ml at −40 mm Hg of lower body negative pressure (Fig. 2). Tilting at 80° was also associated with an increase ($p < 0.01$) in plasma norepinephrine from basal supine levels. After diltiazem therapy there was no significant difference in basal supine norepinephrine levels or in norepinephrine levels after graded lower body negative pressure. However, the norepinephrine response to tilting after diltiazem therapy was greater ($p < 0.01$) than that before therapy.

Basal levels of plasma renin activity and aldosterone as well as levels after graded lower body negative pressure and tilt were similar before and after diltiazem (Fig. 3). Both plasma renin activity and aldosterone levels were increased ($p < 0.05$) after −40 mm Hg lower body negative pressure. In addition, there were plasma renin activity and aldosterone responses to tilt ($p < 0.05$) before and after diltiazem therapy.

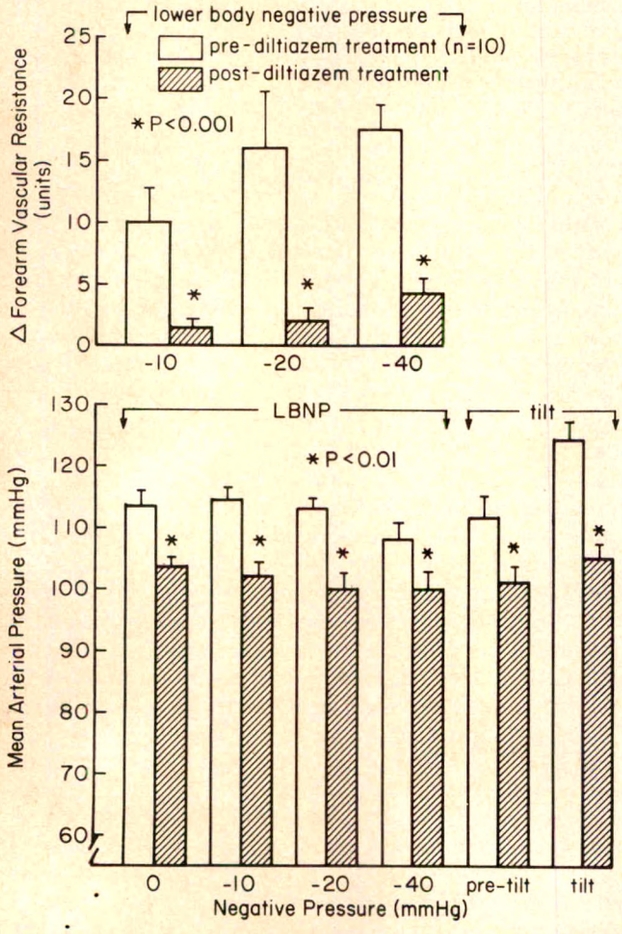

FIGURE 1. Mean ± standard error of the mean response of forearm vascular resistance and mean arterial pressure to graded lower body negative pressure in 10 men with mild to moderate essential hypertension before and after diltiazem therapy. *denotes a statistical difference between the pre-diltiazem and post-diltiazem responses.

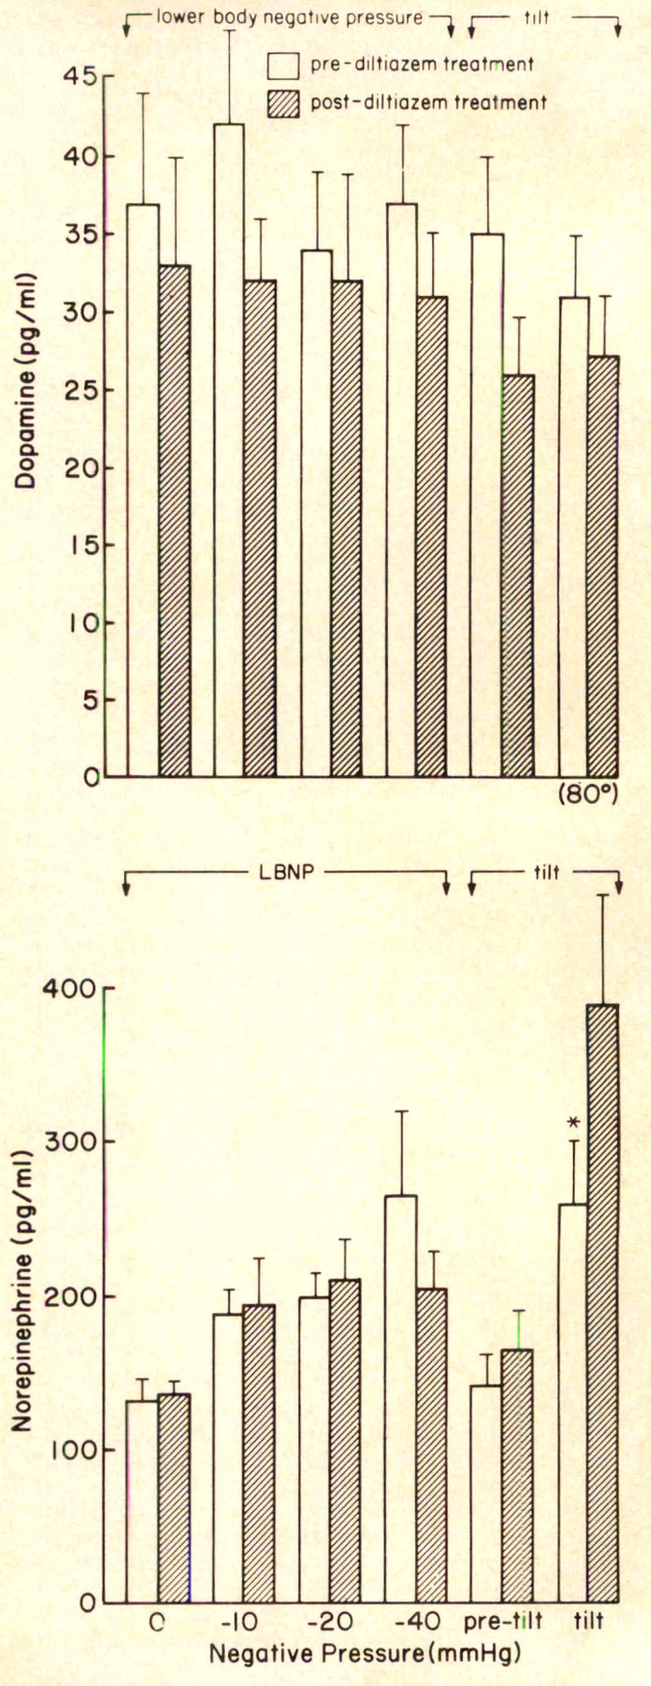

FIGURE 2. Mean ± standard error of the mean response of plasma dopamine and norepinephrine to graded lower body negative pressure in 10 men with mild to moderate essential hypertension before and after diltiazem therapy. *denotes a statistical difference between the pre-diltiazem and post-diltiazem responses.

Discussion

This study demonstrates that in patients with mild to moderate hypertension, graded lower body negative pressure unassociated with blood pressure changes results in sympathetic nervous system activation. Our observations in hypertensive subjects are thus similar to those previously observed in normotensive subjects.[19,25] Goldsmith et al[19] have observed that in normotensive subjects forearm vascular resistance during lower body negative pressure was accompanied by an increase in plasma norepinephrine. Kiowski and Julius[25] observed an increase in plasma norepinephrine during transient occlusion of venous return from the lower extremities. Our data are also consistent with those of Sundlöf and Wallin,[14] who found a consistent increase in multiunit sympathetic activity in recordings from the muscle branches of the medium nerve after lower body negative pressure in normotensive subjects.

Thus, unloading of low pressure cardiopulmonary mechanoreceptors, without associated changes in sinoaortic baroreceptor activity, results in heightened activity of the sympathetic nervous system. The mechanism of increased plasma norepinephrine levels is probably via decreased input from cardiopulmonary receptors with vagal afferents, deactivation of which in animals leads to increased sympathetic activity.[26]

After tilt there was also an increase in plasma norepinephrine that was seen in association with lower body negative pressure. This observation concurs with the results of previous studies[27–29] that have established the importance of sympathetic nervous system activation, and increases in plasma norepinephrine levels, in maintenance of blood pressure, especially in response to posture changes. The sympathetic activity response to tilt appears to be mediated primarily through activation of sinoaortic baroreceptors and afferent pathways, which inhibit the same neuronal pools of the vasomotor center as does afferent input from cardiopulmonary receptors.[30,31] A lack of epinephrine and dopamine response to graded lower body negative pressure and upright tilt suggests that, in contrast to peripheral sympathetic release of norepinephrine, adrenal medullary release of catecholamines is not mediated by cardiopulmonary sinoaortic baroreflexes.

In vitro studies have shown that the release of catecholamines from the adrenal medulla in response to a variety of secretogogues is calcium-dependent.[32,33] Norepinephrine release from noradrenergic neurons is also calcium-dependent because the transport of secretory granules to the cell surface, fusion of the granules with surface membrane and subsequent exocytosis utilize a contractile process that is regulated by calcium and cyclic nucleotides.[34] In vitro studies showed that diltiazem, presumably through its Ca^{++} flux inhibitory action, reduced adrenal medullary catecholamine release in response to several secretagogues.[34] In contrast to in vitro evidence that diltiazem might decrease catecholamine secretion, Inonye et al[35] reported that diltiazem therapy increased plasma norepinephrine and plasma renin activity levels in hypertensive patients. Our findings—that diltiazem therapy had no effect on basal supine levels of norepinephrine, epinephrine or dopamine—are in agreement with another recent report of no change in plasma norepinephrine or epinephrine after diltiazem therapy in normotensive subjects.[11] Further, we observed no effect of diltiazem on plasma norepinephrine responses to graded lower body negative pressure. Diltiazem therapy was associated with an enhanced plasma norepinephrine response to tilt, probably related to a baroreceptor-modulated increase in efferent sympathetic traffic owing to a lower post-diltiazem blood pressure after tilt.

There was a strong correlation between the decrease in forearm vascular resistance and the decrease in ar-

FIGURE 3. terial blood pressure in our patients with mild to moderate hypertension. Diltiazem therapy inhibited the vascular reactivity response to lower body negative pressure without affecting the plasma norepinephrine response. These observations suggest that the effects of diltiazem in reducing blood pressure are due to a reduction in the postjunctional action of norepinephrine on vascular smooth muscle contractility. These observations are consistent with the idea that the sympathetic nervous system affects intracellular calcium levels by opening slow calcium channels, an effect modulated through α_1 and α_2 adrenoceptors.[6,7] It has been previously observed that calcium levels in human platelets are elevated in hypertensive subjects.[7] It has also been observed that, in clinical settings, the increased intracellular free calcium levels can be decreased by calcium antagonists and the decrease in intracellular calcium relates directly to the decrease in blood pressure.[36]

There is considerable in vitro evidence that Ca^{++} has significant effects on renin and aldosterone secretion.[37–39] Ca^{++} flux inhibitors have been reported to increase plasma renin activity[37] and decrease aldosterone[39] secretory responses to various secretogogues. In the clinical setting, diltiazem therapy has been reported to increase plasma renin activity acutely in normotensive subjects[11] and after long-term therapy in hypertensive subjects.[35] Our observations—that diltiazem therapy did not affect basal supine plasma renin activity or lower body negative pressure and tilt-related increase in plasma renin activity—are in agreement with those of Aoki et al[40] in normotensive and hypertensive subjects. In the present study, diltiazem therapy had no effect on plasma aldosterone levels or on aldosterone responses to graded lower body negative pressure and tilt.

This is the first report of a renin and aldosterone response to lower body negative pressure and to tilting in patients with hypertension. Our observation of a renin response to lower body negative pressure supports prior observations of plasma renin responses to venous pooling of blood in legs caused by thigh cuff inflation[25] and lower body negative pressure.[41] The increase in renin release that occurs with assumption of the upright posture probably results from the reflex increase in sympathetic activity induced by the blood volume shift to the lower limbs.[42–44] The basis for this conclusion is the absence of any postural increase in renin during head-up tilt in animals with denervated kidneys[42] and in normal subjects after β-adrenergic blockade[44] or under the influence of antigravity devices.[43] The finding of a renin response to lower body negative pressure in this study provides additional evidence that the cardiopulmonary receptor system plays an important role in modulating renin release in response to vascular fluid shifts. Aldosterone responses to lower body negative pressure and tilt probably occur secondary to activation of renal renin release.

Rationale for Calcium Entry–Blocking Drugs in Systemic Hypertension Complicated by Coronary Artery Disease

ROBERT A. O'ROURKE, MD

There is considerable rationale for the use of the calcium entry–blocking drugs for the treatment of hypertension and prevention of recurrent episodes of angina pectoris in patients with systemic hypertension and significant coronary artery disease—the 2 entities commonly occurring together. Calcium entry–blocking drugs improve myocardial blood flow while decreasing myocardial oxygen demand. These agents can be given to most patients with ischemic heart disease and its complications, and are associated with a relatively low incidence of serious adverse effects and toxicity during long-term therapy. They reduce the frequency of anginal attacks, prolong exercise time to ST-segment depression or angina and improve exercise capacity. With long-term therapy, tolerance does not develop as it does in many patients with the "long-acting" nitrates.

Calcium entry–blocking drugs reduce systolic blood pressure in patients with hypertension by a decrease in peripheral vascular resistance and a uniform improvement in blood flow affecting the myocardium, kidney and brain. There are no central nervous system adverse effects and hypokalemia does not occur. Unlike therapy with the β-blocking drugs, chronic treatment with the calcium entry blockers does not reduce the serum level of high-density lipoprotein cholesterol nor increase serum triglyceride concentration. The calcium blockers decrease the arterial blood pressure without increasing intravascular plasma volume and are associated with only a slight increase in reflex-mediated sympathetic activity and heart rate, the latter occurring predominantly with nifedipine.

Calcium entry–blocking drugs provide alternative or preferred therapy to β-blocking agents in patients with a combination of hypertension and angina pectoris. They are likely to be more effective in elderly patients and in blacks and can be prescribed for patients with bronchospastic disease and symptomatic peripheral vascular disease. For many reasons, of the 3 currently available calcium blockers, diltiazem is likely to be the most effective calcium entry blocker for monotherapy in patients with hypertension and ischemic heart disease, although most worldwide experience for this indication has been with nifedipine.

(Am J Cardiol 1985;56:34H–40H)

Systemic hypertension and ischemic heart disease frequently occur in the same patient for several reasons. First, hypertension is a well-known risk factor for coronary atherosclerosis and effective treatment of hypertension reduces the morbidity and mortality resulting from coronary artery disease (CAD), as well as from stroke. Second, several of the diseases or conditions associated with 1 of these 2 common disorders are also independently associated with the other. For example, systemic hypertension often results from chronic renal disease and uremia accelerates coronary atherosclerosis. Also, an increased incidence of both hypertension and symptomatic coronary atherosclerosis is found in patients with obesity, diabetes mellitus or a long history of cigarette smoking. Finally, in patients with severe coronary atherosclerosis and in those with mild to moderate CAD but considerable left ventricular (LV) hypertrophy, hypertension is an important determinant of an increased myocardial oxygen demand. The severity of angina is often reduced in such patients when the systolic blood pressure is lowered by appropriate drug therapy; in many patients anginal episodes actually disappear when the blood pressure is controlled by medical therapy.

Accordingly, many patients with both hypertension and symptomatic CAD will require medical therapy with drugs selected both for their efficacy as antianginal agents and for their ability to reduce the arterial blood pressure at rest and during exercise. This article will focus first on the use of calcium entry–blocking

drugs as antianginal agents and then on the utility of these drugs for the treatment of hypertension complicated by ischemic heart disease.

Calcium Entry Blockers as Antianginal Agents

The desirable characteristics of an antianginal agent are listed in Table I. Each of the currently available calcium entry–blocking drugs—diltiazem, nifedipine and verapamil—has been shown to reduce angina due to coronary artery spasm (variant angina) and to prevent, attenuate or reverse the angiographically demonstrated coronary artery spasm that can be produced in susceptible patients with intravenous ergonovine stimulation.[1–7] Each of these drugs has also been shown to decrease the frequency of angina attacks and to improve exercise tolerance in patients with chronic stable angina.[8–18] During treadmill or bicycle exercise, diltiazem, nifedipine and verapamil increase the exercise time to ST-segment depression (as measured by electrocardiogram monitoring) and prolong the time to the development of angina as well as the total exercise duration. Several studies[19–21] indicate that calcium blockers are as efficacious as β-blocking drugs or "long-acting" nitrates in preventing recurrences of myocardial ischemia in patients with unstable angina, most of whom have angina at rest. In 1 study,[21] nifedipine was particularly effective in the subgroup of patients who tended to show ST-segment elevation on the electrocardiogram during episodes of ischemic chest pain. It is likely that an element of increased coronary vasomotor tone (coronary artery spasm) contributes to myocardial ischemia in many such patients.[22–24]

Although controversy exists as to the primary mechanism, calcium entry blockers probably exert their salutary effects in patients with variant angina, angina at rest and chronic exertional angina by both reducing myocardial oxygen demand and improving coronary blood flow (Fig. 1). The calcium entry–blocking drugs reduce the heart rate-blood pressure product at rest and during exercise: nifedipine decreases arterial blood pressure during exercise, while verapamil and diltiazem reduce heart rate during exercise. Thus, these drugs favorably affect several factors that influence myocardial oxygen demand. Also, calcium blocking drugs cause coronary artery and systemic arterial dilatation and may reverse, blunt or prevent coronary artery vasoconstriction. Therefore, calcium blockers provide effective therapy for patients with variant angina due to coronary artery spasm and may reverse any coronary vasoconstriction in otherwise normal coronary arteries or in the lumen of areas with eccentric coronary artery stenosis; in either case coronary blood flow is improved to areas of myocardial ischemia in patients with chronic exertional angina or unstable angina.

Therapy with a calcium entry blocker is applicable to most patients with ischemic heart disease and its complications. This heterogeneous group of drugs does not produce or worsen symptoms in patients with bronchospastic lung disease or peripheral vascular disease. They can also be given to patients with diabetes mellitus, including those taking insulin. However, they should not be used in patients with severe hypotension or overt congestive heart failure. The differences in potency for various therapeutic actions are useful when administering calcium entry blockers in patients with complications resulting from ischemic heart disease. For example, nifedipine can be used for the treatment of angina in patients with resting bradycardia and first degree atrioventricular (AV) block because it does not produce the same depression of AV conduction and sinoatrial nodal activity in therapeutic doses that occurs with verapamil and to a lesser extent with diltiazem. In patients with severe LV dysfunction who are not in overt heart failure, diltiazem, the calcium blocker with the least depressant effect on LV performance, can be used to treat angina, whereas verapamil in particular is more likely to produce or exacerbate any symptoms of heart failure.

TABLE I Desirable Characteristics of Antianginal Drugs

Improvement of coronary blood flow while decreasing myocardial oxygen demand
Applicability to most patients with ischemic heart disease and its complications
Relatively low incidence of adverse effects and toxicity during long-term therapy
No development of tolerance during long-term treatment
Favorable modification of risk factors for progressive coronary atherosclerosis

Adverse effects occur with the calcium entry blockers, but most of these reactions are relatively minor and unassociated with an increase in either morbidity or mortality; true drug toxicity is uncommon. The incidence of adverse effects is by far the greatest with nifedipine because of its marked strong arterial vasodilator effects in therapeutic doses and the resulting reflex increase in sympathetic activity. Dizziness, cutaneous flushing and marked postural hypertension are particularly common adverse effects seen with it. Constipation is most common with verapamil, and all 3 cause peripheral edema, frequently transient in nature. Diltiazem is associated with a relatively small incidence of adverse effects but with all 3 drugs, untoward effects are more common at high doses. The development of advanced AV block or se-

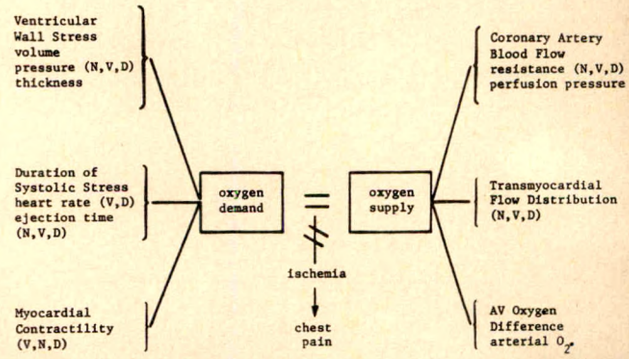

FIGURE 1. Favorable effects of currently available calcium entry–blocking drugs on the determinates of myocardial oxygen demand and coronary blood flow. N, V and D = nifedipine, verapamil and diltiazem, respectively, in order of relative potency.

vere heart failure with the use of these drugs is uncommon if patients who have preexisting first degree AV block, peripheral conduction abnormalities or evidence of heart failure before therapy are excluded. These complications occur more commonly when a calcium entry blocker is combined with a β-blocking drug, particularly when the calcium blocking drug is verapamil. Interestingly, the calcium entry–blocking drugs when used alone have been shown to actually improve the LV ejection fraction and the response of the LV ejection fraction to exercise in patients in whom myocardial ischemia is improved. Calcium entry blockers can also affect LV performance by arterial vasodilatation, which reduces afterload and improves the LV ejection fraction, despite the direct negative inotropic effect (Fig. 2).[12,15]

Neither tachyphylaxis nor partial tolerance appears to develop to the antianginal effects of the calcium entry blockers. Petru et al[25] have demonstrated the same antianginal efficacy of diltiazem in patients with chronic exertional angina 16 months after the initiation of therapy that was present at the end of 2 weeks of treatment (Fig. 3). Similar data indicate that verapamil and probably nifedipine also provide effective long-term therapy for chronic stable angina.[26]

Calcium entry–blocking drugs decrease peripheral vascular resistance and by lowering the blood pressure in patients with hypertension are effective in reducing this risk factor for coronary atherosclerosis. These agents do not adversely affect serum lipids. They do not reduce the serum level of high-density lipoprotein cholesterol or increase the serum triglyceride concentration, which often occurs in patients receiving long-term therapy with either β blockers or thiazide diuretics.

Comparison with Other Antianginal Drugs

The calcium entry–blocking drugs provide alternative or additional therapy to nitrates for variant or unstable angina as well as alternative or additional therapy to nitrates or β-blocking drugs for chronic stable angina. The nitrates act primarily by reducing venous return, LV volume and arterial pressure, thus decreasing LV wall stress, a major determinant of myocardial oxygen demand at rest and during exercise.[27] In addition, they reverse any coronary vasoconstriction in the large coronary arteries or that involves the lumen in areas with eccentric coronary artery stenosis, thereby promoting improved coronary blood flow to areas of myocardial ischemia.[28] There is also some evidence that nitroglycerin improves collateral coronary blood flow in patients with severe coronary artery stenosis.[27]

There are several advantages to using nitrate therapy in patients with angina pectoris. First, there is considerable clinical experience with them, and their efficacy is well proven. This is particularly true with regard to the use of short-acting nitrates to interrupt episodes of angina pectoris. Second, the nitrates, like the calcium entry blockers, prevent and may reverse any element of coronary artery vasoconstriction contributing to episodes of myocardial ischemia. Third, nitrates frequently improve LV performance by reducing LV end-diastolic volume and thus pulmonary venous pressure. They also may improve the LV ejection fraction by afterload reduction. Fourth, the adverse effects of nitrate therapy are well defined and

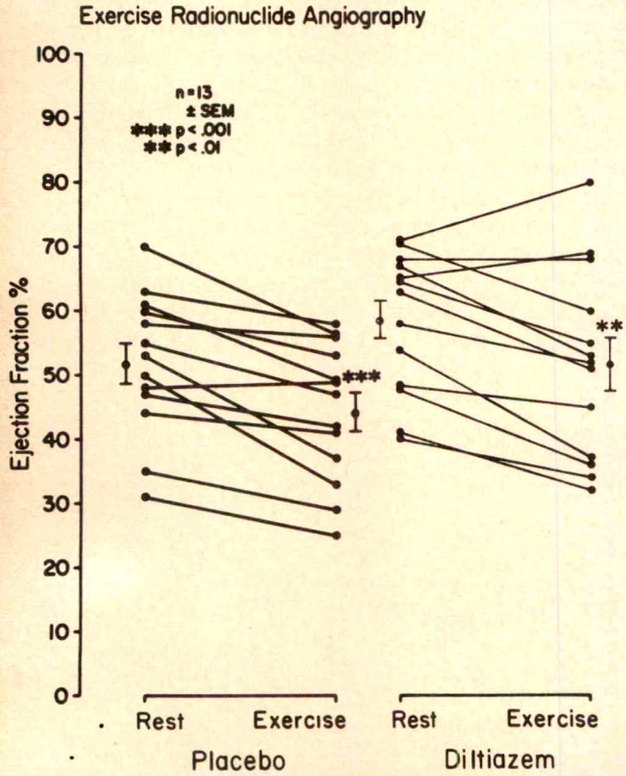

FIGURE 2. Radionuclide-determined left ventricular ejection fraction at rest and during exercise on placebo, **left,** and diltiazem, **right,** in 13 patients with chronic stable angina. SEM = standard error of the mean. Reproduced with permission from Circulation.[15]

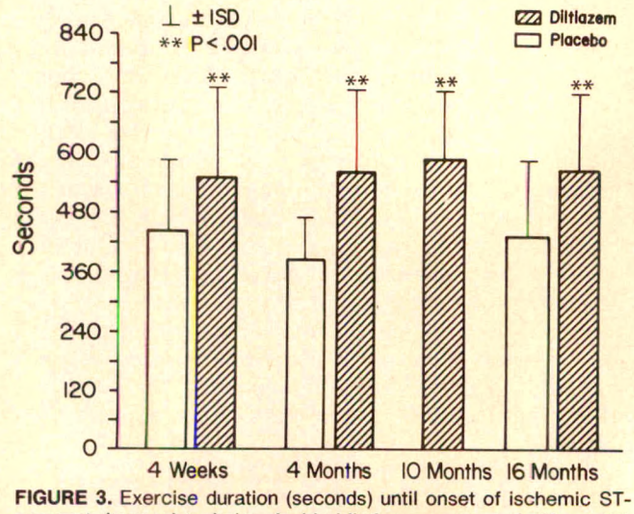

FIGURE 3. Exercise duration (seconds) until onset of ischemic ST-segment depression during double-blind crossover study (4 weeks) and during long-term follow-up at 4, 10 and 16 months in 8 patients who completed the long-term study. Values are for each diltiazem-treatment week versus all comparable placebo-treatment weeks. SD = standard deviation. Reproduced with permission from Am Heart J.[25]

there is minimal interaction with other drugs, except for the potentially additive hypotensive effect that may occur when nitrates are added to other vasodilator drugs. Finally, nitrate therapy is relatively inexpensive compared with other antianginal drugs.

There are, however, several limitations to nitrate therapy. First, currently available preparations have not been proven to provide effective once-daily or even twice-a-day therapy. This is also the case with calcium entry blockers. Importantly, partial to complete tolerance often develops in patients with angina pectoris. The duration of the reduction in arterial blood pressure and the increase in exercise tolerance after each dose lasts for a shorter duration during chronic nitrate therapy compared with the salutary effect observed early after the initiation of treatment.[29] Tolerance does not occur with the long-term use of a calcium entry blocker. Third, there are few discrete quantitative endpoints for dosage adjustments with nitrate therapy. Adverse effects are relatively common with nitrate therapy, and a reduction in the arterial diastolic blood pressure to below 60 mm Hg can often reduce coronary blood flow to areas of coronary artery stenosis that are already dilated due to local hypoxia and are "pressure dependent" for adequate perfusion.

The β-blocking drugs produce their salutary effects primarily by decreasing several determinants of myocardial oxygen demand at rest and particularly during exercise in patients with angina pectoris.[30–32] The primary effect of the β blockers is to attenuate the heart rate response to endogenous catecholamines during exercise or other forms of stress. The decrease in systemic arterial pressure at rest, and to a greater extent during exercise, is a lesser factor except in patients with systemic hypertension. The slight reduction in myocardial contractility produced by the β blockers is a relatively minor factor in reducing the myocardial oxygen demand, as is also the case with calcium blockers. The β-blocking drugs have little effect on the coronary blood supply to ischemic myocardium although a redistribution of blood flow to the subendocardial area has been demonstrated in experimental animals. In contrast, the calcium entry blockers cause coronary artery dilatation.

There are several advantages to the use of β-blocking drugs in the treatment of patients with chronic stable angina, and their beneficial effect has been well demonstrated. First, a decrease in myocardial oxygen demand at rest and during exercise has been clearly defined as the mechanism of action, and the heart rate response to exercise can be used as a therapeutic endpoint for therapy. Second, the potentially adverse effects of β blockers and their interactions with other drugs are well known. Third, specific drugs are available with sufficiently long half-lives for once-a-day therapy, which improves patient compliance. Finally, partial tolerance and tachyphylaxis, such as occur with nitrates, seldom result from β-blocker therapy.

However, there are several contraindications to the use of β-blocking drugs that modify or prevent their use in many patients. These include overt congestive heart failure, advanced AV block and documented sinoatrial nodal disease. Because all β-blocking drugs, including the "cardioselective" ones, affect both β_1 and β_2 receptors when given in moderate to high dosages, β-blocking drugs often worsen symptoms in patients with bronchospastic disease or symptomatic peripheral arterial disease. By contrast, no exacerbation of symptoms occurs with the calcium entry blockers. Also, β-blocking drugs tend to increase serum triglyceride levels and reduce the serum level of high-density lipoprotein cholesterol, thus worsening lipid abnormalities that are often present in patients with ischemic heart disease and for whom they are a risk factor. Calcium entry–blocking drugs produce no change in serum lipid levels.

Several clinical studies have been performed comparing 1 or more calcium entry–blocking drugs with a β blocker, usually propranolol, or with a "long-acting" nitrate, usually isosorbide dinitrate, in patients with chronic stable angina.[10,11,18,32–37] In general, the calcium entry blockers appear to be equally or possibly more effective in the treatment of patients with angina pectoris, depending on the patient population studied and the doses used. "Step-therapy" for angina pectoris is now popular, and many physicians prescribe 1 antianginal drug initially and then add a second and subsequently a third medication for patients with an unsatisfactory reduction in the frequency of anginal attacks. However, no formula for using a particular sequence of drug therapy (for example, "long-acting" nitrate, then β blocker, then calcium blocker) has been proven better than another (for example, calcium or β blocker first, then a nitrate, then 1 of the remaining group of drugs).

Combined therapy with a calcium entry–blocking drug and a β-blocking agent or a "long-acting" nitrate produces a greater salutary result than single drug therapy in some patients with chronic stable angina. In certain patients, "triple therapy" for angina (calcium blocker plus β blocker plus nitrate) provides an even greater reduction in the frequency of angina and improves exercise tolerance more than with monotherapy. However, adverse effects are likely to be more common in combined therapy and deleterious results may occur. When calcium entry–blocking drugs and nitrates are combined, the reduction in systemic vascular resistance is additive and severe postural hypotension results in some patients. Accordingly, the dosage of 1 vasodilator often must be reduced when the second agent is added, and careful measurement of the supine and upright blood pressure before and after therapy is important.

Both β and calcium entry blockers decrease sinoatrial nodal activity, prolong AV conduction and depress LV performance. Accordingly, combination therapy with drugs from these 2 groups is likely to produce marked bradycardia, advanced AV block or LV failure in certain patients, particularly when verapamil is the calcium entry blocker. Verapamil has the greatest depressant effect on sinoatrial nodal activity, AV conduction and LV performance.[38–41] However, such complications appear to be infrequent and are unlikely to occur in patients who have no manifestations of sino-

TABLE II Additional Desirable Characteristics of Antianginal, Antihypertensive Drugs

Decrease in total peripheral resistance
Efficacy in elderly patients
No expansion of intravascular (plasma) volume
Minimal reflex cardiac stimulation
Once- or twice-a-day dosage
Relatively low cost for effective therapy

atrial nodal disease, AV block or congestive heart failure before the initiation of combined antianginal therapy.

Use of Calcium Entry–Blocking Drugs for Patients with Concomitant Hypertension in Ischemic Heart Disease

Additional characteristics that would be desirable in an antianginal drug used to treat concomitant systemic hypertension are listed in Table II. The calcium entry–blocking drugs have been used for several years in Europe for this purpose and are being used with increased frequency as monotherapy for patients with a combination of hypertension and recurrent episodes of angina pectoris.[42–47]

The ideal antihypertensive and antianginal drug should reduce arterial pressure primarily by decreasing total peripheral resistance with a relatively uniform decline in vascular resistances in the major organ circulations of the body, including the kidney, heart and brain. The calcium entry–blocking drugs possess this characteristic and increase coronary blood flow through coronary artery dilatation while decreasing the systemic blood pressure—a major determinant of LV wall stress—and thus myocardial oxygen demand. Because angina in patients with hypertension occurs more frequently with increasing age, an ideal antihypertensive and antianginal drug would be one that is proven effective in elderly patients and in blacks as well as whites. The efficacy of calcium entry–blocking drugs is not dependent on the status of the renin-angiotensin-aldosterone system; they are effective antihypertensive agents regardless of renin levels. Patients with a combination of hypertension and ischemic heart disease frequently have depressed LV performance and often develop signs and symptoms of left-sided heart failure. Therefore, in such patients it would seem appropriate to use antihypertensive, antianginal drugs that reduce peripheral vascular resistance and thus promote forward blood flow without expanding the intravascular (plasma) volume, the latter being a potentially deleterious effect of many antihypertensive drugs.[48–50] In the studies by Olivari et al[42] calcium entry–blocking drugs produced no intravascular volume expansion, no alteration in glomerular filtration rate and no change in plasma renin activity in a group of hypertensive patients in whom blood pressure was importantly reduced. Muiesan et al[45] found similar results in groups of hypertensive patients treated with nifedipine or verapamil.

Myocardial oxygen consumption is directly related to heart rate, and it is desirable to avoid tachycardia in patients with angina pectoris, because of potential myocardial ischemia. It would be desirable to use drugs for the treatment of combined hypertension and angina pectoris that produce minimal reflex stimulation of the sympathetic nervous system. The reduction in blood pressure produced by the calcium entry–blocking drugs elicits a baroreceptor reflex-mediated indirect increase in heart rate that is more commonly observed with nifedipine than with either verapamil or diltiazem. The latter 2 calcium entry blockers have a greater direct depressant effect on sinoatrial nodal activity in therapeutic doses than does nifedipine. Klein et al[44] showed that both diltiazem and nifedipine were effective in controlling mild to moderate chronic essential hypertension. The average heart rate during therapy was not significantly increased by nifedipine and was lowered by diltiazem. Nifedipine therapy was associated with a reflex activation of the sympathetic nervous system in all patients and resulted in an increase in plasma norepinephrine concentration and tachycardia in some. Moreover, diltiazem has the advantage of lowering blood pressure, reducing afterload and increasing stroke volume with a less pronounced increase in catecholamines and without reflex tachycardia. Further, adverse effects with diltiazem were uncommon and long-term therapy was well tolerated.

It would be useful to have a therapeutic agent for monotherapy in patients with hypertension complicated by ischemic heart disease that would provide effective therapy when given once or twice a day. Currently, calcium entry blockers are not available in a preparation that permits once- or twice-a-day dosing. However, new formulations of the currently available drugs that permit twice-a-day therapy are being used in clinical research studies, and other calcium entry–blocking drugs with longer half-lives should be available soon. At this time, the daily cost of therapy with calcium entry blockers is higher than either β blockers or many of the other antihypertensive drugs. The single exception is the angiotensin-converting enzyme inhibitor, captopril.

Considering the various hemodynamic effects of the 3 currently available calcium entry blockers, diltiazem will most likely become the most effective agent for monotherapy in patients with both hypertension and angina pectoris. It has fewer untoward effects than either nifedipine or verapamil, and it produces the least depression of LV performance and rarely causes reflex tachycardia. Verapamil is more likely to cause or exacerbate LV dysfunction or bradycardia, and nifedipine has the highest incidence of adverse effects, often producing reflex tachycardia.

Comparison with Other Antianginal-Antihypertensive Drugs

The β-adrenergic receptor–blocking drugs have both antianginal and antihypertensive effects. They have been used effectively as monotherapy or combined with other antihypertensive drugs in the treat-

ment of patients with both angina pectoris and hypertension. There are β-blocking drugs available for once- or twice-a-day therapy in patients with hypertension and ischemic heart disease. However, the β-blocking drugs are frequently ineffective in controlling blood pressure in blacks and in elderly patients. Calcium entry–blocking drugs may be better for this purpose. Also, the β-blocking drugs do not decrease total peripheral vascular resistance and their use is often associated with central nervous system untoward effects. In addition, the β-blocking drugs may exacerbate bronchospasm in patients with chronic lung disease or intermittent claudication in patients with generalized atherosclerosis. Finally, long-term therapy with β-blocking drugs tends to result in an increase in serum triglyceride levels while reducing levels of high-density lipoprotein cholesterol. Calcium entry–blocking drugs do not have this potentially adverse effect.

Diuretics are frequently used as first-step therapy for patients with systemic hypertension, including those with coincident CAD. It is now recognized that hypokalemia, serious arrhythmias and sudden death are potential complications of diuretic therapy in patients with systemic hypertension, particularly in those with severe coronary atherosclerosis. In addition, long-term administration of thiazide diuretics often produces the abnormal lipid profile seen with β-blocking drug therapy.

Other antihypertensive drugs that are primary vasodilators do not exert a favorable effect on blood flow to ischemic myocardium and may even precipitate angina pectoris by either causing reflex tachycardia (e.g., hydralazine) or by reducing the perfusion pressure to myocardium distal to severe coronary artery stenoses without augmenting coronary blood flow. Whether coronary artery "steal" is produced frequently by calcium entry–blocking drugs is a subject of current investigation.

Comparison of Diltiazem and Nifedipine for Both Angina Pectoris and Systemic Hypertension

WILLIAM H. FRISHMAN, MD, SHLOMO CHARLAP, MD, JEFFREY GOLDBERGER, MD, BRUCE KIMMEL, MD, JACK STROH, MD, FRANCESCA DORSA, BA, LUCY ALLEN, RPh, and JOEL STROM, MD

In a randomized, double-blind, placebo-controlled crossover trial, diltiazem and nifedipine were compared in 10 patients with stable angina pectoris and mild to moderate hypertension (supine diastolic blood pressure ≥90 mm Hg). Patients received placebo for 2 weeks, then increasing doses of diltiazem (90 to 360 mg/day) or nifedipine (30 to 120 mg/day) in 3 daily divided doses over 2 weeks, followed by 1 week of therapy at the maximal dose, a 1-week placebo "washout," then crossover to the other drug. Heart rate and blood pressure at rest and during exercise, anginal frequency, nitroglycerin consumption and treadmill exercise tolerance were assessed.

Compared with placebo, anginal frequency and nitroglycerin consumption were reduced with both diltiazem and nifedipine ($p < 0.01$) and exercise tolerance was increased with both drugs ($p < 0.01$). Standing blood pressure at rest was reduced by diltiazem and nifedipine (146.6 ± 11.4/97.7 ± 5.3 mm Hg at placebo, baseline reduced to 129.6 ± 15.2/79.5 ± 13.7 mm Hg with diltiazem, and to 122.2 ± 9.9/82.0 ± 7.1 with nifedipine, $p < 0.01$ for both). Compared with placebo, diltiazem and nifedipine also reduced exercise diastolic blood pressure ($p < 0.01$), but not systolic blood pressure. Diltiazem lowered the heart rate at rest from 88.5 ± 14.4 beats/min at placebo baseline to 79.7 ± 17.9 beats/min ($p < 0.01$); the heart rate with diltiazem was 11 beats/min lower than that with nifedipine ($p < 0.05$). Both diltiazem and nifedipine had similar effects on the heart rate-blood pressure product at rest and during exercise. Both drugs were well tolerated. Thus, diltiazem and nifedipine appear equally effective and safe in patients with both hypertension and angina pectoris by relieving angina, improving exercise tolerance and reducing elevated blood pressure.

(Am J Cardiol 1985;56:41H–46H)

Systemic hypertension and coronary artery disease (CAD) are common disorders; it is therefore not unexpected that the prevalence of both conditions together is high. The incidence of these disorders concomitantly is further increased by the fact that hypertension is an important risk factor for CAD. Thus, single agents that are capable of treating both disorders, allowing for improved patient compliance, are of particular interest. To date, the therapeutic agents of choice in the management of patients with both systemic hypertension and angina pectoris have been the β-adrenergic–blocking drugs.[1] In a prior placebo-controlled, double-blind study, verapamil was shown to be a safe and effective alternative to propranolol in treating such patients.[2] Because diltiazem and nifedipine have also been shown to be effective in each condition when they occur separately,[3–10] an evaluation of their efficacy in patients with both conditions was in order. We now report the findings of a placebo-controlled, double-blind, randomized, crossover trial comparing the antihypertensive and antianginal effects of diltiazem and nifedipine in a group of patients with both stable angina pectoris and systemic hypertension.

Methods

Patient selection: Ten ambulatory patients (7 men and 3 women) with stable angina pectoris and mild to moderate systemic hypertension were entered into the study after written and informed consent was obtained. The patients represented a subgroup from a larger study population with angina pectoris. The mean patient age was 55.7 years (range 44 to 69). The diagnosis of angina pectoris was established by: (1) clinical history of classic stable angina pectoris characterized by the occurrence of precordial chest pain, pres-

TABLE I Effects of Placebo, Nifedipine and Diltiazem on Heart Rate (HR) and Blood Pressure (BP) at Rest in Patients with Angina Pectoris and Hypertension

	Baseline (Placebo)	Nifedipine	Diltiazem	Statistical Significance: Placebo vs Nifedipine	Statistical Significance: Placebo vs Diltiazem	Statistical Significance: Nifedipine vs Diltiazem
Three-minute standing HR (beats/min)	88.5 ± 14.4	90.9 ± 17.9	79.7 ± 17.9	NS	p <0.01	p <0.05

Diastolic BP (mm Hg)	97.7 ± 5.3	82.0 ± 7.1	79.5 ± 13.7	p <0.001	p <0.001	NS
Rate-pressure product (beats/min × mm Hg × 10^2)	129.8 ± 22.1	111.3 ± 24.2	104.3 ± 30.4	p <0.01	p<0.01	NS

NS = not significant.

sure or distress (which had been stable for at least 3 months), usually precipitated by exercise or emotional stress and relieved by sublingual nitroglycerin, rest or removal of emotional stress, (2) demonstration of a positive ischemic response on 2 occasions to a standardized, multistage treadmill exercise test, defined as anginal pain or at least 1 mm of flat or downward-sloping ST-segment depression, 0.08 seconds after the J point or (3) both 1 and 2.

The diagnosis of CAD was made on the basis of at least 1 of the following: coronary angiography (75% luminal narrowing of at least 1 major coronary vessel) in 6 patients, and previous myocardial infarction in 6 patients. No patient had had coronary artery bypass surgery. Systemic hypertension was documented in all patients by history and by a 3-minute supine diastolic blood pressure (using Korotkoff phase V) >90 mm Hg at the end of the placebo run-in period.

Experimental design: During the study, patients were permitted sublingual nitroglycerin tablets (0.6 mg) as the only antianginal medication other than the test drugs. Nitroglycerin tablets were used as needed to treat anginal episodes and were not used prophylactically. Digitalis, propranolol, long-acting nitrates and antiarrhythmic drugs were withdrawn at least 2 weeks before study entry. Patients received no additional antihypertensive therapy during the trial.

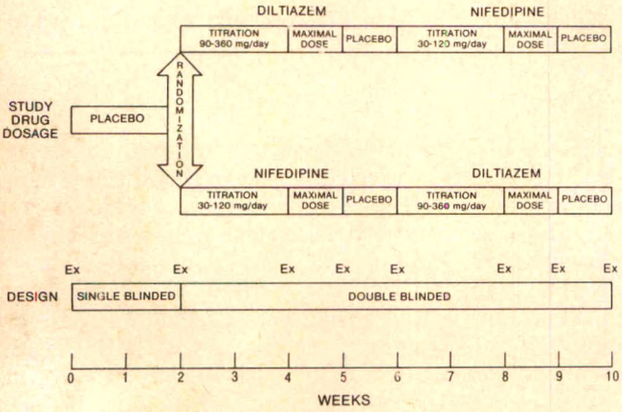

FIGURE 1. Study design: a 2-week, single-blind, placebo phase; double-blind randomization into diltiazem and nifedipine treatment groups; a 2-week dose-titration phase; followed by 1 week of maximal therapy. After a 1-week withdrawal schedule onto placebo, patients were crossed over to the other treatment schedule for a 2-week dose-titration phase and 1 week of maximal therapy. This was followed by a 1-week withdrawal schedule onto placebo. Standardized multistage graded exercise (Ex) tests were performed at the times indicated. Study drug doses are indicated for the dose-titration phase.

The blind protocol (Fig. 1) consisted of an initial 2-week, single-blind, placebo run-in period. During this time each patient received 2 placebo capsules 3 times a day, identical in appearance to the study medications. Patients who fulfilled all the inclusion criteria at the end of the second placebo run-in week entered the first drug treatment phase. During this phase, each patient received progressively increasing doses of either diltiazem (starting at 30 mg, 3 times a day, and increasing to 120 mg, 3 times a day) or nifedipine (starting at 10 mg, 3 times a day, and increasing to 40 mg, 3 times a day) as tolerated over the first 2 weeks of therapy. Patients were titrated to maximal dose or to appearance of adverse effects, and were then maintained on this dosage for an additional week. After the initial crossover period, the patients were abruptly discontinued from active therapy and were placed on placebo for 1 week. After completion of this second placebo period, each patient was crossed over to the other medication regimen, and the 3-week treatment period, as well as 1-week placebo withdrawal phase, was repeated.

Clinical observations: All patients kept a detailed daily record of anginal attacks and nitroglycerin tablets consumed. Supine and standing blood pressure and heart rate determinations were made once at the same time of the day, 2 to 5 hours after ingestion of placebo or the experimental drug. In this study, normalization of blood pressure was defined as a standing diastolic blood pressure of <90 mm Hg that was also reduced by at least 10 mm from the baseline value. Only the analyses of weeks 2, 5 and 9, when patients were on their highest doses of medication, are presented.

Exercise tolerance tests: Each patient underwent serial exercise tests at weeks 0, 2, 4, 5, 6, 8, 9 and 10 (Fig. 1). Multistage treadmill exercise testing consisted of sequential 3-minute stages of increasing workload, speed and elevation, using the Naughton protocol.[11] Tests were performed at approximately the same time of day and day of the week for each patient, when patients were in the postabsorptive state—approximately 2 to 5 hours after a dose. The stage at which each patient was started was individualized to attempt to have the patient reach exercise termination within 3 to 6 minutes. The stage for initiation was identical for each exercise test performed by a patient.

During exercise, blood pressure was measured every 3 minutes and lead V_5 was continuously monitored on an oscilloscope. The endpoints of exercise were either the onset of angina, an ST-segment change of ≥4 mm in the absence of anginal pain, a significant decrease in systolic blood pressure during exercise, the development of severe ventricular dysrhythmia (increased frequency of ventricular premature complexes), the occurrence of left bundle branch block or a high degree of atrioventricular block.

Measurements of heart rate, systolic and diastolic blood pressure and ST-segment displacement were obtained at the

last minute of each stage of exercise. The electrocardiogram was continually assessed for the occurrence of arrhythmias, and the rate-pressure product (systolic blood pressure × heart rate) was calculated. At the endpoint of exercise, each test was also analyzed for the maximal heart rate, systolic blood pressure and rate-pressure product achieved, total exercise duration (seconds), ST-segment displacement (mm) and reason for exercise limitation. The exercise work, expressed in kilopondmeters (kpm), was calculated from the formula: work (kpm) = $\sin\alpha \times$ speed (m/sec) × body weight (kg) × exercise time (seconds) × 10^{-3}, where α is the angle of inclination of the treadmill.

Plasma drug levels: Specimens for diltiazem and nifedipine plasma levels were obtained approximately 2 to 5 hours after drug ingestion, just before exercise testing. Drug levels for diltiazem were assessed with high-pressure liquid chromatography (Marion Laboratories, personal communication); those for nifedipine, with gas chromatography (Biodecision Laboratories, personal communication).

Statistical analysis: Group data are expressed as mean ± standard deviation in the text and tables, and as mean ± standard error of the mean in the figures. Differences were analyzed by the 2-tailed t test and were considered significant at the $p < 0.05$ level.

Results

All 10 patients who entered the study completed the trial and were titrated to dose levels of nifedipine, 10 to 40 mg, 3 times a day (mean 96 mg/day) and diltiazem 90 to 120 mg, 3 times a day (mean 342 mg/day). Mean blood levels of diltiazem at maximal doses were 279 ng/ml (range 96 to 507) and for nifedipine, 213 ng/ml (range 58 to 351). The plasma levels were within the therapeutic range for both drugs.

Effects on blood pressure and heart rate at rest: Results are shown in Table I and Figures 2 and 3. Compared with placebo, both diltiazem and nifedipine therapy produced significant reductions in supine and standing systolic and diastolic blood pressures. No significant differences between the antihypertensive effects of the 2 drugs were observed.

Normalization of blood pressure occurred with nifedipine in 8 of 10 patients; 8 of 10 responded to diltiazem in similar fashion (7 responded to both drugs). One patient, whose placebo baseline diastolic blood pressure was 100 mm Hg, had a diastolic blood pressure of 90 mm Hg on nifedipine (30 mg, 3 times a day) and 92 mm Hg on diltiazem (120 mg, 3 times a day). Another patient, who normalized on nifedipine, responded to diltiazem (120 mg, 3 times a day) with a diastolic blood pressure drop from 106 mm Hg baseline to 90 mm Hg. One more patient, who normalized on diltiazem, responded to nifedipine (40 mg, 3 times a day) with a diastolic blood pressure drop from 100 to 96 mm Hg on therapy. The patients who did not respond to active drug therapy had therapeutic plasma levels of the respective drugs. Overall, no correlation between plasma levels and blood pressure response was seen.

Diltiazem caused a reduction in standing heart rate ($p < 0.01$), but not supine heart rate. It also reduced the standing heart rate when compared with nifedipine ($p < 0.05$). Nifedipine caused a small, insignifi-

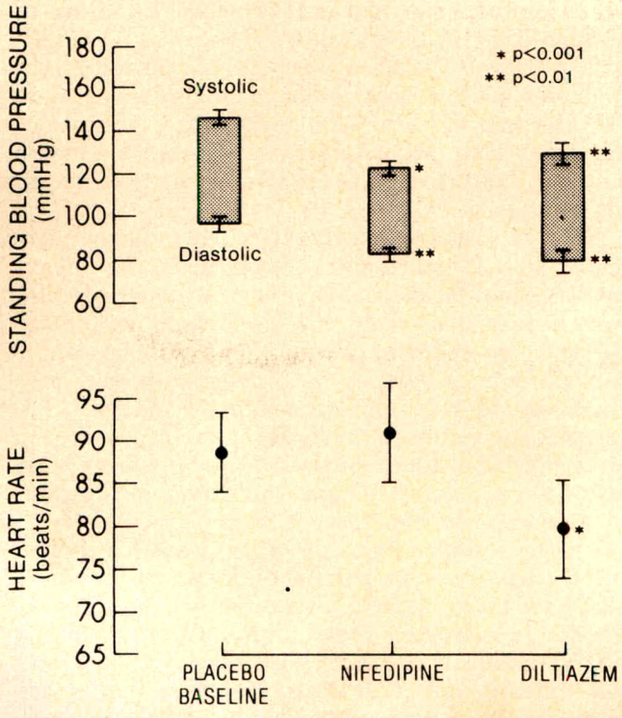

FIGURE 2. Standing blood pressure and heart rate at rest during placebo, nifedipine and diltiazem therapy. Comparisons are made with placebo baseline.

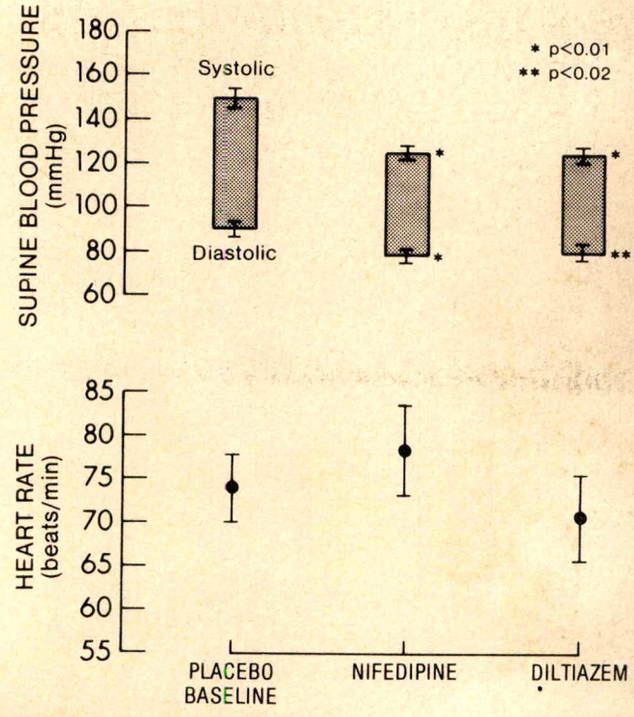

FIGURE 3. Supine blood pressure and heart rate at rest during placebo, nifedipine and diltiazem therapy. Comparisons are made with placebo baseline.

TABLE II Effects of Placebo, Nifedipine and Diltiazem on Anginal Symptoms, Exercise Tolerance and Exercise Variables

	Baseline (Placebo)	Nifedipine	Diltiazem	Statistical Significance: Placebo vs Nifedipine	Statistical Significance: Placebo vs Diltiazem	Statistical Significance: Nifedipine vs Diltiazem

TABLE III Effects of Placebo, Nifedipine and Diltiazem on the Rate-Pressure Product (beats/min × mm Hg × 10^2) Measured at Rest, Submaximal Exercise and Peak Exercise in Patients with Angina Pectoris and Hypertension

	Placebo	Nifedipine	Diltiazem	Statistical Significance: Placebo vs Nifedipine	Statistical Significance: Placebo vs Diltiazem	Statistical Significance: Nifedipine vs Diltiazem
Baseline	129.8 ± 22.1	111.3 ± 24.2	104.3 ± 30.4	p <0.01	p <0.01	NS
After 2 minutes of exercise	200.9 ± 45.5	160.7 ± 29.9	153.8 ± 27.3	p <0.01	p <0.001	NS
Peak	221.2 ± 43.2	214.8 ± 46.4	209.1 ± 44.2	NS	NS	NS

NS = not significant.

cant increase in standing and supine heart rate when compared with placebo.

Effects on angina pectoris: These results are shown in Table II and Figure 4. There was a reduction in the number of anginal attacks per week reported in patient diaries with both drugs. There was no significant difference between drugs in the magnitude of improvement in angina, although nifedipine was more effective than diltiazem in reducing nitroglycerin consumption from placebo baseline. Plasma drug levels were not indicative of the degree of improvement in anginal frequency.

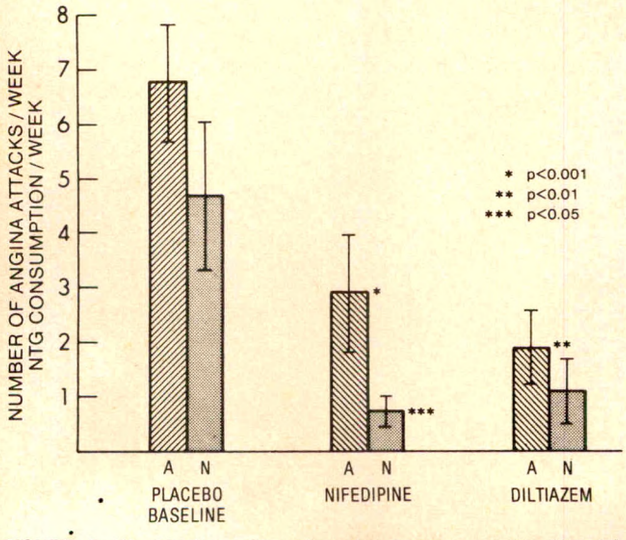

FIGURE 4. Weekly frequency of angina pectoris attacks (A) and nitroglycerin consumption (N) during placebo, nifedipine and diltiazem therapy. Comparisons are made with placebo baseline. NTG = nitroglycerin.

Effects on exercise variables: The results are given in Tables II and III and Figures 5 and 6. Significant increases in total exercise time and calculated exercise work were demonstrated with both nifedipine and diltiazem compared with placebo. There were no significant differences between the 2 drugs with respect to these variables. No differences in the maximal ST-segment deviation at exercise endpoint were seen among placebo, diltiazem and nifedipine. Plasma drug levels did not correlate with the degree of improvement in exercise tolerance.

The rate-pressure product at rest was lower than placebo baseline with both nifedipine and diltiazem ($p < 0.01$ for both). After 2 minutes of exercise, this reduction in mean rate-pressure product from placebo was maintained with both nifedipine ($p < 0.01$ and diltiazem ($p < 0.001$), with no significant difference observed between the active drugs. There was an observable blunting in the mean rate of rise of the rate-pressure product from rest to the 2-minute measurement in the nifedipine and diltiazem treatment

groups. At maximal exercise, there were no significant differences in mean rate-pressure products in the placebo, nifedipine and diltiazem groups. Neither nifedipine nor diltiazem significantly altered the peak mean systolic blood pressure or the peak mean heart rate when compared with placebo. However, the peak mean heart rate was higher ($p < 0.05$) in the nifedipine group compared with the diltiazem group. Peak mean diastolic blood pressure was maintained at a lower level with diltiazem ($p < 0.01$) and nifedipine ($p < 0.02$) than with placebo.

Adverse effects: Adverse effects reported by the patients on each of the drugs are seen in Table IV. Nine of 10 patients on nifedipine and 8 of 10 patients on diltiazem experienced at least 1 adverse effect. Overall, patients taking diltiazem had less complaints. One patient taking diltiazem (360 mg/day) developed Mobitz type I block and was withdrawn from dilitiazem therapy at the end of 2 weeks of active therapy.

TABLE IV Adverse Effects Reported by Patients While Taking Nifedipine and Diltiazem

	Nifedipine	Diltiazem
Palpitations	3	5
Shortness of breath	1	0
Heart block	0	1
Constipation	1	1
Facial flushing	1	0
Headache	3	2
Dizziness	3	2
Nervousness	4	1
Ankle edema	4	0
Other	8	3
Total	28	15

Discussion

Both diltiazem and nifedipine have potent antihypertensive actions.[3–5] The results of this double-blind, placebo-controlled study suggest that the drugs are also effective antihypertensive agents in patients with both angina pectoris and hypertension. Both drugs significantly reduced resting systolic and diastolic blood pressure in the standing and supine positions. All patients exhibited some reduction in blood pressure; in 8 of 10 patients on each drug the blood pressure was normalized.

One must be very careful when using arterial vasodilator drugs in hypertensive patients with angina pectoris, because these drugs often produce a sympathetically mediated reflex tachycardia, which may precipitate angina pectoris. Several studies have reported worsening of anginal symptoms in some patients on nifedipine therapy,[7,12–14] possibly related to reflex tachycardia. In our study, nifedipine produced no major change in heart rate, perhaps explaining how well the drug was tolerated. Diltiazem, which is a less potent vasodilator than nifedipine, also has direct depressant activity on sinoatrial automaticity,[10,15] and thus usually leaves the heart rate unchanged or decreased, as was observed in this study.

Effects on angina and exercise tolerance: Nifedipine and diltiazem are widely used in the treatment of patients with angina pectoris of effort.[6–10] In this study, both drugs were equally effective in reducing anginal frequency and in improving exercise tolerance in hypertensive patients with angina pectoris.

The maximal rate-pressure product observed during exercise on both diltiazem and nifedipine therapy was not significantly different from that during placebo. The drugs also did not reduce the level of ischemia at peak exercise, because similar degrees of ST-segment depression developed on active therapy and placebo. These observations suggest that the main pharmacotherapeutic action of these drugs in improving exercise tolerance is by reduction of myocardial oxygen consumption.[16] Therefore, the rate-pressure products at submaximal levels of exercise were reduced.

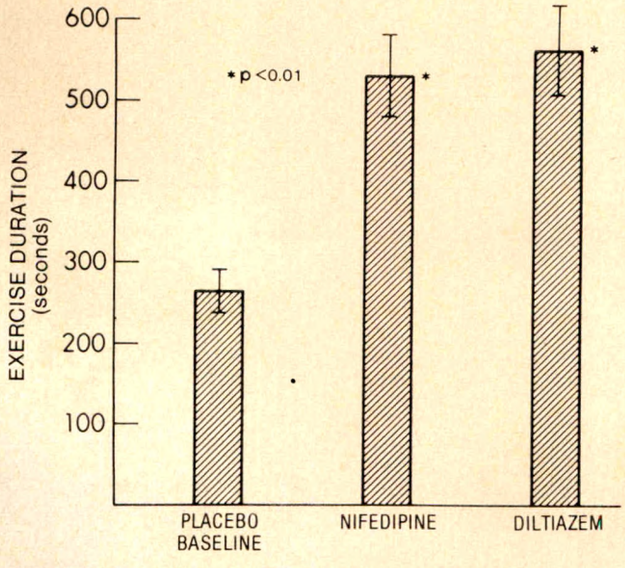

FIGURE 5. Treadmill exercise duration during placebo, nifedipine and diltiazem therapy. Comparisons are made with placebo baseline.

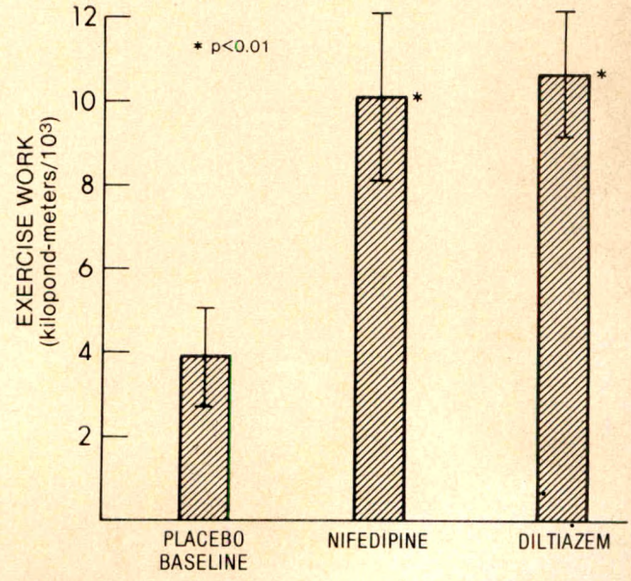

FIGURE 6. Treadmill exercise work during placebo, nifedipine and diltiazem therapy. Comparisons are made with placebo baseline.

Adverse effects: Diltiazem appears to be a better tolerated drug than nifedipine, with about half the number of reported adverse effects. One patient developed Mobitz type I heart block on diltiazem therapy, but this resolved with withdrawal of the drug. No other adverse effect necessitated cessation of therapy.

Clinical implications: In this study of hypertensive patients with angina pectoris, diltiazem and nifedipine were both shown to be safe and effective therapies for reducing attacks of angina pectoris, improving exercise tolerance and reducing elevated blood pressure. It is now evident that calcium channel entry–blockade can provide an alternative monotherapy to patients with both angina pectoris and systemic hypertension. Drug blood levels can be used to ensure compliance to treatment, but appear not to be helpful in predicting a clinical response. Because such patients are often on multiple medical regimens, simplification is often the key to improving patient compliance and, consequently, therapeutic outcome. Clinical experience is still needed for assessing possible interactions when calcium channel–blocking drugs are used with other agents commonly used in patients with both angina pectoris and systemic hypertension.

Long-Term Renal and Systemic Effects of Calcium Entry Blockers in Normotensive and Experimental Hypertensive Dogs

BEN G. ZIMMERMAN, PhD, and JOAN L. GOERING, BA

The effect of diltiazem administered as a sustained infusion (10 to 15 μg/kg/min) was studied in 3 groups of conscious instrumented dogs: 4 normotensive, 5 Goldblatt hypertensive (GH) and 4 deoxycorticosterone acetate-salt treated Goldblatt hypertensive (DSGH) dogs. Mean arterial blood pressure, left renal blood flow and heart rate were monitored, and the plasma renin activity was determined in a control session and after 3 to 5 days of diltiazem infusion in the normotensive and after 5 to 8 days of infusion in the 2 hypertensive groups. Pressor and renal blood flow responses to phenylephrine, norepinephrine and angiotensin II were also determined in the control session and on the last day of the diltiazem infusion. Mean arterial blood pressure was found to be decreased at the 5 to 8-day interval in the DSGHs and in the GHs, but the change in the latter group was not statistically significant. Mean arterial blood pressure was unchanged in the normotensives. Renal vascular resistance was decreased by diltiazem in the normotensive group at 3 to 5 days and in the DSGHs at 1 to 2 days. Heart rate was not significantly affected by diltiazem in the hypertensive groups, but was increased in the normotensive group at the 1 to 2-day interval. Plasma renin activity tended to increase in the hypertensive, but not in the normotensive dogs. Pressor and renal blood flow responses to all the agonist agents tested were decreased in the presence of diltiazem. The hypotensive effect of diltiazem was more prominent in the conscious DSGHs than in the normotensive dogs or GHs; a decrease in renal vascular resistance was seen in both the normotensive and DSGH groups. Hypotension in these animals may be related at least in part to depression of vasoconstrictor stimuli.

(Am J Cardiol 1985;56:47H–51H)

Calcium entry blockers possess pharmacologic actions that make them potentially important agents for the treatment of essential hypertension. When administered on a long-term basis to hypertensive patients, nifedipine has a sustained hypotensive action; however, early in the treatment period, it evokes reflex increases in heart rate, plasma norepinephrine and renin levels.[1] Its blood pressure-lowering effect is attributable to relaxation of vascular smooth muscle—hence the vasodilatation—but a secondary action appears to intervene, which attenuates the baroreflex-induced tachycardia and renin release.[1,2] The mechanism of this secondary action has not been delineated. Because of the close relation between the kidney and hypertension, the actions of calcium entry blockers on renal function and hemodynamics are of particular interest. Recently, several renal effects of these agents have been uncovered; they appear to differ from those of classic vasodilator agents and may contribute to the overall usefulness of these blockers as antihypertensive agents. Systemic as well as intrarenal arterial administration of calcium entry blockers in short-term experiments have revealed a renal vasodilator action accompanied by increases in glomerular filtration rate and sodium excretion.[3–5] Interference with the intrarenal processes of tubuloglomerular feedback and renal blood flow autoregulation have also been demonstrated.[1,6] These effects are presumably due to the blockade of the action of calcium, upon which these processes may depend. Because most renal studies with the calcium entry blockers have been carried out for short time periods, little is known about the long-term renal effects of these agents.

The present investigation compared the renal hemodynamic and hypotensive effects of a sustained infusion of the calcium entry blocker diltiazem in normotensive and renovascular hypertensive dogs. We

also wished to determine the effects of diltiazem on heart rate, plasma renin activity and response to pressor agents.

Methods

Experiments were conducted on 8 mongrel dogs of both sexes, weighing 19.7 to 25.4 kg each. The animals were quarantined until deemed healthy and immunized before use. Four normotensive and 6 Goldblatt hypertensive (GH) dogs were studied (Goldblatt hypertension was induced in 2 of the normotensive dogs). Chronic catheters (PE 50 tubing) were implanted in the femoral artery and vein for monitoring systemic arterial blood pressure and the intravenous injection of drugs, respectively. Arterial blood samples were withdrawn for plasma renin activity determination, using a previously reported radioimmunoassay technique.[7] Renal blood flow was measured from an implanted Zepeda blood flow probe (5 to 6 mm) in the left renal artery, connected to a Zepeda (SWF-4) electromagnetic flowmeter.[8] Mean arterial blood pressure and renal blood flow were monitored in the dogs while conscious and lying on a padded table. Experiments were conducted in the normotensive dogs after they had recovered from the surgical procedures. Two-kidney, 1-clip GH dogs were prepared by constriction of the right renal artery with an adjustable Goldblatt clamp. The clamp was tightened until renal blood flow was reduced by 75 to 80% of the control value as measured by electromagnetic flowmetry. An infusion pump (Infusaid Corp.) was implanted subcutaneously in the instrumented dogs in order to administer diltiazem chronically intravenously. A description of this technique was previously published.[9] The method of implantation (B. Wigness, unpublished observations) was as follows. A 10-cm incision was made parallel to the cranial edge of the infraspinous fossa, usually on the left side, beginning at the dorsal boundary of the scapula. A pocket for accommodating the pump was achieved by blunt dissection between the cutaneous trunci and the latissimus dorsi muscles. The pump was inserted and positioned between these muscles. Four ligatures were passed through loops on the pump using a surgical needle, and were tied carefully into the underlying muscle so as not to puncture the thorax. With the pump anchored into place, the catheter from the pump was led subcutaneously, the deep circumflex iliac or brachial vein was cannulated and the catheter was tied in place. Penicillin streptomycin (Vetycil) was injected into the pocket and the skin incision was sutured closed. The pump was filled with sterile water before implantation, and was refilled through the injection port when necessary. Water was infused for several days while the dog recovered from the implantation surgery. Infusion rates ranged from 6 to 13 ml/day, and the capacity of the pump was 50 ml. All operative procedures were carried out under aseptic conditions and penicillin streptomycin was administered on the day of surgery and when necessary thereafter.

Protocol: Experiments on the conscious dogs were begun by monitoring mean arterial blood pressure and renal blood flow until stable, and heart rate was then determined either by counting the arterial pulse or with a cardiotachometer (Beckman). These parameters were recorded on a Beckman R511 polygraph. A single 3-ml arterial sample was withdrawn for determination of plasma renin activity. Mean arterial blood pressure and renal blood flow responses to consecutive intravenous injections of phenylephrine hydrochloride (4 and 8 μg/kg), norepinephrine bitartrate (0.5 and 1 μg/kg) and angiotensin II (0.0125 and 0.05 μg/kg) were elicited to establish control pressor and renal vasoconstrictor effects. After this control experiment, the pump was emptied of its aqueous content with a syringe connected to a needle inserted into the injection port, which was palpated through the skin. Fifty milliliters of diltiazem solution at body temperature was used to prime the pump to provide a dose of 10 to 15 μg/kg/min throughout the period of drug treatment, which usually lasted 5 to 7 days. The pump was refilled periodically in order to provide a continuous infusion of the drug. The duration of infusion varied somewhat because of the few technical difficulties that developed in the course of the study. On the final day of drug infusion, the experiment with the agonist agents was repeated. This experimental protocol was used in the normotensive dogs, in the GH dogs (beginning $\bar{X} = 27$, range 11 to 67 days postclipping) and in the GH dogs given deoxycorticosterone acetate (DOCA)-salt (DSGHs) (5 mg DOCA and NaCl, 10 g/day).

Drugs used were l-norepinephrine bitartrate, l-phenylephrine hydrochloride, angiotensin II amide and diltiazem hydrochloride. Analysis of variance was performed on the data, using orthogonal contrasts to test for differences between means. Values are presented as the mean or mean ± standard error, and statistical significance was assumed at the level of $p < 0.05$.

Results

Effect of long-term infusion of diltiazem on blood pressure, renal vascular resistance, heart rate and plasma renin activity in normotensive and hypertensive dogs: Diltiazem infused at 10 to 15 μg/kg/min for 3 to 5 days in normotensive dogs pro-

duced the changes in mean arterial blood pressure and the other parameters presented in Figure 1 and Table I. Variable changes in mean arterial blood pressure were seen in the normotensive dogs, with a decrease obtained in only 1 of 4. There was, however, a significant decrease in renal vascular resistance after 3 to 5 days of the diltiazem infusion. Heart rate increased in 3 of these 4 dogs during both time intervals, but the change was not significant. Plasma renin activity was not affected by diltiazem.

In GH dogs, diltiazem had a small effect on mean arterial blood pressure (Fig. 2 and Table I). At 1 to 2 days, only 1 of 5 dogs failed to respond, and at 5 to 8 days there was a modest decrease in mean arterial blood pressure in all. During diltiazem infusion, heart rate was significantly increased in the early interval, but returned to control levels at 5 to 8 days (Table I). Renal vascular resistance was not significantly affected by diltiazem in GH dogs. At 5 to 8 days, plasma renin activity was increased in 4 of the 5 dogs, but due to the variable change, the increase was not statistically significant.

Because diltiazem tends to increase plasma renin activity, and this is believed to antagonize the hypotensive effect of the drug,[2] we attempted to suppress the activity of the renin-angiotensin system in the GH dogs by administration of DOCA-salt. This approach was only partially successful because plasma renin activity was decreased to a negligible level in only 1 of 4 (Table I). Nevertheless, the DSGH dogs responded more consistently to diltiazem than the untreated GH dogs (Fig. 3 and Table I). Mean arterial blood pressure was reduced at 1 to 2 days in 3 of the 4, and was decreased in all 4 dogs at 5 to 8 days of the infusion. The rapid reversal of the hypotensive effect of diltiazem is seen in Figure 3. When the pump ran out of drug on day 4 of the infusion in dog no. 35, blood pressure promptly returned to the control level, and when the infusion was resumed, hypotension was reinstituted. Heart rate was variably affected by diltiazem in this group of animals, but plasma renin activity was increased significantly after 5 to 8 days of infusion.

Effect of long-term infusion of diltiazem on agonist-induced pressor and renal blood flow responses in normotensive and hypertensive dogs: Pressor (as Δ mm Hg) and renal blood flow responses (as percentage of decrease in renal blood flow) to phenylephrine, norepinephrine and angiotensin II in these groups of dogs are depicted in Figures 4 to 6. Responses were elicited in the control experiment and on the final day of diltiazem infusion (3 to 5 days in normal dogs and 5 to 8 days in hypertensive dogs). The magnitude of both the pressor and renal blood flow responses was similar in a given group of dogs; however, the renal blood flow response to angiotensin II tended to be greater in normotensive than hypertensive dogs. This probably reflected lower plasma renin activity in the normotensive group, because it is well known that the vascoconstrictor effect of angiotensin II is inversely related to plasma renin activity.[10,11] Generally, there was a uniform depression of both the pressor and renal blood flow response by diltiazem; however, the decrease in the pressor responses was not statistically significant in the normotensive group.

Discussion

Most previous investigations of the effect of calcium entry blockers on blood pressure and renal function

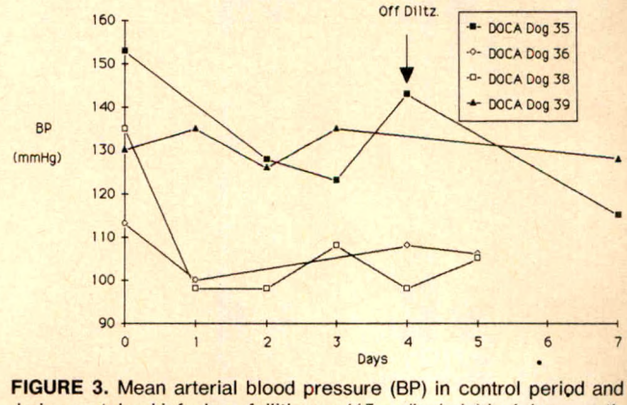

FIGURE 3. Mean arterial blood pressure (BP) in control period and during sustained infusion of diltiazem (15 μg/kg/min) in 4 deoxycorticosterone acetate (DOCA)-salt treated Goldblatt hypertensive dogs. Infusion ran out in dog no. 35 on day 4 (off Diltz.) and was resumed on day 5.

have dealt with their acute effects during intravenous or intrarenal arterial infusion.[3–5,12] It has generally been found that these agents decrease mean arterial blood pressure and increase heart rate, renal blood flow, glomerular filtration rate, sodium excretion and plasma renin activity. The vasodilator action of these agents has been considered responsible, either directly or indirectly, for these effects. Proportionately greater dilatation of the afferent than the efferent arterioles in the kidney would explain the increase in glomerular filtration rate. A selective antagonism by nisoldipine on the afferent arteriolar vasoconstriction caused by norepinephrine has also been reported.[13] Because certain calcium entry blockers, such as nifedipine and diltiazem, are used to treat hypertension, it is necessary to better understand their long-term influence on the cardiovascular system. Although the vasodilator action of these drugs accounts for the short-term cardiovascular and renal effects seen, there may be secondary actions that come into play to bring about sustained hypotension, and these are less well understood. We examined the long-term effects of diltiazem in the present study by using an intravenous infusion of a relatively high dose, 10 to 15 μg/kg/min, of the drug for about a week. Although some of our conclusions must be tempered because of the small number of animals studied, there appeared to be a difference in the response of the normotensive and hypertensive dogs to the sustained effect of diltiazem. Whereas the normotensive dogs did not exhibit a hypotensive effect, there was a modest though variable hypotensive response in both the GH and DSGH dogs. Some hypertensive dogs responded well while others exhibited only a slight decrease in mean arterial blood pressure.

Because the plasma renin activity was increased in both groups of hypertensive dogs (in 8 of 9 experiments in these 2 groups), it is likely that this was a factor contributing to their variable hypotensive response. Absence of an increase in the plasma renin activity in the normotensive group suggests that, in

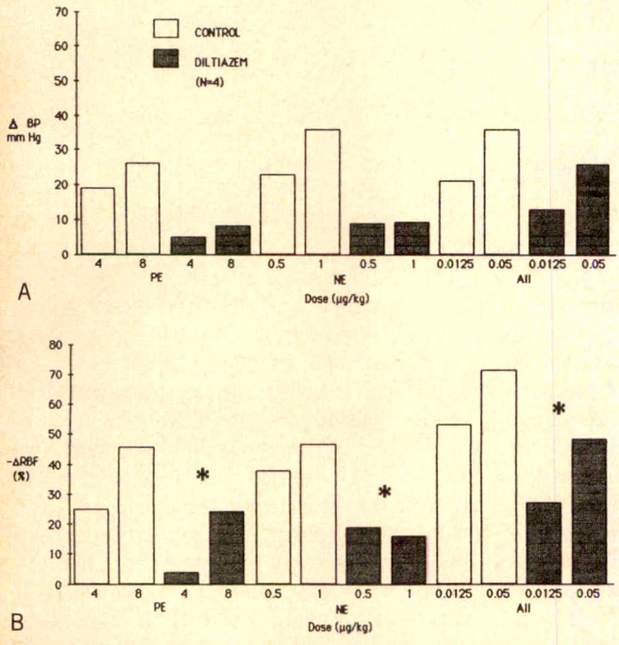

FIGURE 4. A, Blood pressure (Δ BP mm Hg) and **B,** renal blood flow (% Δ RBF) changes elicited by phenylephrine (PE), norepinephrine (NE) and angiotensin II (A II) administered intravenously in normotensive dogs before and during infusion of diltiazem (10 to 15 μg/kg/min).

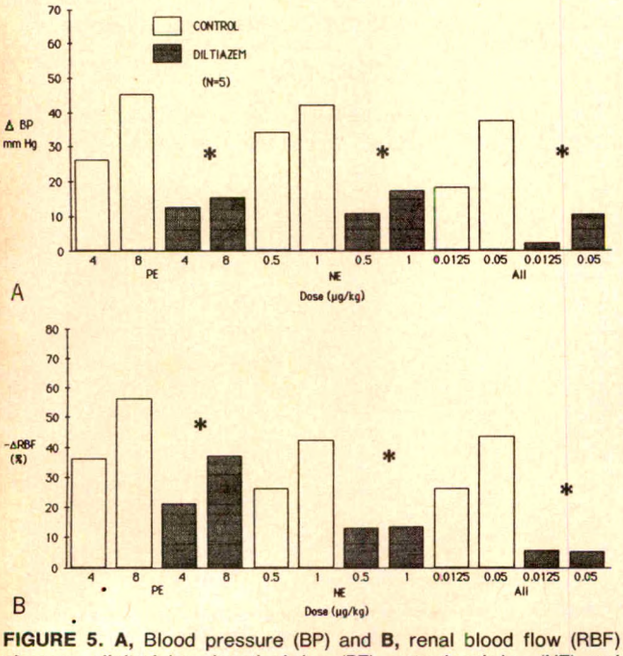

FIGURE 5. A, Blood pressure (BP) and **B,** renal blood flow (RBF) changes elicited by phenylephrine (PE), norepinephrine (NE) and angiotensin II (A II) administered intravenously in Goldblatt hypertensive dogs before and during infusion of diltiazem (15 μg/kg/min).

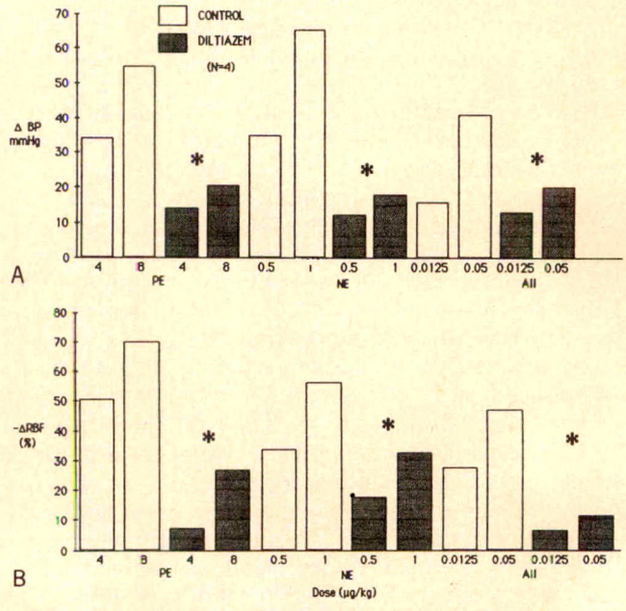

FIGURE 6. A, Blood pressure (BP) and **B,** renal blood flow (RBF) changes elicited by phenylephrine (PE), norepinephrine (NE) and angiotensin II (A II) administered intravenously in deoxycorticosterone acetate (DOCA) salt treated Goldblatt hypertensive dogs before and during infusion of diltiazem (10 to 15 μg/kg/min).

GH dogs, activation of the renin angiotensin system may be more sensitive to decreased calcium. It is known that renin release can be stimulated by removal of calcium from the medium perfusing of the kidney;[14,15] however, the relation between calcium and renin release in hypertension is not well defined. As with other investigators, we also found an increase in heart rate early after initiating administration of the calcium entry blocker in normotensive and GH dogs. This transient tachycardia was presumably due to the baroreflex evoked by the fall in mean arterial blood pressure. A variable renal vasodilator response to diltiazem was obtained in 2 of the 3 groups of dogs. In the DSGH dogs at 1 to 2 days and in normotensive dogs at 3 to 5 days, a significant decrease in renal vascular resistance was obtained during diltiazem administration. A generalized depression of reactivity to pressor agents was associated with the sustained decrease in mean arterial blood pressure caused by diltiazem. There have been numerous reports of marked attenuation of the pressor and vasconstrictor response to various agonists in vivo and to the contractile response of isolated vascular preparations in vitro by calcium entry blockers.[16–18] These observations were made during short-term administration of the drug, and it has not been substantiated that this is also a long-term effect. Some claim that the response to α_2 adrenoceptor agonists, and not α_1 adrenoceptor agonists, is depressed;[18] however, this point is controversial.

We also found a marked depressant effect of the renal vasoconstrictor response to pressor agents with short-term administration of diltiazem (unpublished observations). This depression of vascular reactivity appears to persist throughout the entire period of drug infusion as noted in the present study. In none of the 3 groups of animals was there evidence of a differential effect on the pressor agents studied. There was some variability within the animals, but the degree of depression of both the pressor and renal blood flow response to norepinephrine, phenylephrine and angiotensin II was about the same. Because these 2 adrenergic amines stimulate mainly α_1 adrenoceptors, and angiotensin II acts on its own receptors, inhibition of the vascular contractile response owing to stimulation at these sites was uniformly demonstrated. We did not see any clear indication of a relatively selective depression of the response to angiotensin II, as has been reported by others.[12] However, because our series was small, such an effect might have been uncovered by increasing the number of experiments. Also, the selectivity of action of calcium entry blockers may be a dose-dependent phenomenon. It would appear that the hypotension and decrease in renal vascular resistance that we observed in the present study are closely related to the depressed vascular reactivity obtained with diltiazem.

The Kidney and Effective Antihypertensive Therapy

NORMAN K. HOLLENBERG, MD, PhD

Whether or not the kidney is involved in the genesis of hypertension in an individual patient, it becomes a major determinant of the response to antihypertensive therapy once a treatment strategy is adopted. The major mechanisms through which the kidney influences blood pressure are renin release and sodium retention, either together or separately, but additional mechanisms may also contribute. When sodium intake is restricted or a diuretic is used, the reactive increase in plasma renin activity makes a substantial contribution to limiting the blood pressure fall. When vasodilators or agents that block the sympathetic nervous system are used, sodium retention plays an important role. Among newer agents, the effectiveness of calcium channel blockers, converting enzyme inhibitors and perhaps dopamine analogs reflects, for reasons that differ from 1 class of agent to another, a special action on the kidney that limits the reactive renal response to the reduction in blood pressure. Treatment strategies that address the problem of the renal response are more likely to be effective than approaches that avoid or ignore it.

(Am J Cardiol 1985;56:52H–55H)

Much of the strategy in designing antihypertensive therapy—a substantial amount of which was initially empirical—has involved the renal compensatory responses to the agents, whichever drug therapy was selected. Direct acting arteriolar vasodilators, for example, have always provided an attractive approach to the treatment of hypertension, because in most patients the hemodynamic defect responsible for the elevated pressure is an increase in peripheral resistance, at least partly mediated by vasoconstriction.[1] The use of nonspecific vasodilators has largely been limited by activation of compensatory systems,[2] including a prominent renal response that involves both retention of sodium and increase in renin release. This article will focus on some of the more practical implications of our increased understanding of the kidney's role in sustaining hypertension, however it is initiated.[3] A review of the functional abnormalities involving the renal blood supply in essential hypertension,[4–10] the role of newer pharmacologic agents in therapy[5,9–13] and the nature and extent of the reactive responses that often limit the effectiveness of therapeutic agents[2,5,12,14–16] is necessary to achieve this goal.

Investigators studying hypertension have several reasons for their long-standing interest in the renal blood supply as it affects glomerular filtration rate (GFR), sodium handling by the kidney and renal renin release. First, a reduction in renal blood flow due to renal artery stenosis is the most common curable form of secondary hypertension and is still believed by many investigators to contribute in some patients to the pathogenesis of essential hypertension. Second, whatever factors initiate the hypertension process in an individual patient, it is becoming evident that a renal response must be involved in order to sustain the elevated blood pressure.[3] Third, it is also becoming clear that the effectiveness of antihypertensive therapy, whatever agent is used, is determined to a substantial degree by the renal response. Finally, the continuing damage to the renal microvasculature by uncontrolled severe hypertension previously accounted for one of the major complications—uremia. The sharp reduction in the frequency of this complication is one of the triumphs of modern antihypertensive therapy.

A decrease in renal perfusion is common in essential hypertension; recent estimates suggest that about two-thirds of patients with essential hypertension have an inappropriately decreased renal blood flow.[7] Multiple lines of evidence now suggest that a functional disturbance—active vasoconstriction—plays a role in the abnormal renal perfusion and GFR in patients with essential hypertension. Renal perfusion varies in a moment-to-moment fashion much more in patients with essential hypertension than in normal subjects,

an abnormality that must be due to active vasoconstriction.[7] Renal vasomotion is also increased in essential hypertension.[8] Moreover, when nonspecific vasodilators such as acetylcholine are administered into the renal artery, renal blood flow increases much more strikingly in patients with essential hypertension than in normal subjects.[4] With this potentiated renal vascular response, abnormalities in the renal arteriogram are reversed, often completely, by the vasodilators.

To the extent that such a functional abnormality involving the renal blood supply plays a role in the individual patient, one might anticipate that suitable doses of an appropriate vasodilator agent would reverse these abnormalities and thus improve renal perfusion and filtration rate. The renal response to therapy is conditioned to a major degree by both the relative influence of the fall in blood pressure and the direct and indirect effects of the therapeutic agent on the kidney.

Restriction of sodium intake is the simplest available therapeutic approach to hypertension. This maneuver reduces renal blood flow and GFR in animals and in man. The evidence is unequivocal that angiotensin-induced renal vasoconstriction, consequent to the reactive increase in renin release, accounts entirely for renal vasoconstriction.[6,17] There is now clear evidence that when diuretics are used as therapy, the reactive increase in plasma renin activity limits the fall in blood pressure.[11] Thus, it is reasonable to conclude that the decrease in renal blood flow and GFR induced by a diuretic is also angiotensin-mediated.

Because activation of the renin-angiotensin system plays such a central role in limiting the response to restriction of sodium intake and diuretics, it was reasonable to suspect that the addition of a β-adrenergic blocking agent—many of which block renin release when it is mediated by β-adrenergic receptors in the juxtaglomerular apparatus—would reverse the impact of restriction of sodium intake and diuretics on the kidney.[2] Unfortunately, propranolol, the most widely used and studied β-adrenergic blocking agent, directly induces renal vasoconstriction, apparently through an action on an α-adrenergic receptor in the kidney.[18] A propranolol-induced decrease in renal blood flow, with a parallel reduction in GFR, sodium retention and a reduced ability to handle sodium load, has also been well documented in man.[19] Although this renal response could be due to a decrease in cardiac output induced by the negative inotropic and chronotropic actions of these agents on the heart, it actually occurs with doses insufficient to influence cardiac output.[10] A similar renal response has been documented for a wide variety of β-adrenergic blocking agents including oxprenolol, pindolol, acebutolol, atenolol and dichloroisoproterenol.[9]

Renal vasoconstriction, however, is not an inevitable result of β-adrenergic blockade. Nadolol, a long-acting hydrophilic β-adrenergic blocking agent, induces a dose-related *increase* in renal blood flow over the dose range at which it decreases heart rate and thus cardiac output in man.[10] As opposed to the propranolol-induced decrease in sodium excretion, antinatriuresis did not occur with nadolol in the dog; indeed, nadolol increased sodium excretion (K. Duchin, unpublished observations). The clinical implication of this observation may be the remarkable frequency with which nadolol achieves goal blood pressure.[20] The Veterans Administration Cooperative Study Group reported that 77% of a large group of white subjects with mild to moderate essential hypertension achieved goal blood pressure with nadolol,[20] substantially more than achieved good blood pressure in a parallel study by the same Study Group on responses to other β blockers.[13]

What impact do the "nonspecific" vasodilators have on the kidney? This general class includes hydralazine, minoxidil, diazoxide, sodium nitroprusside and, in part, trimethapan.[15,16] The spectrum of their renal response is wide, but certain features are common to all. Despite the range of direct actions on the renal blood supply, sodium retention—often striking—occurs with *all*[15,16] and is the factor that limits their therapeutic efficacy.[14] The mechanism of the sodium retention has not yet been clearly delineated, but it is evident that the systemic response, especially the drop in blood pressure, plays an important role. For example, diazoxide is a potent renal vasodilator when infused into the renal artery, and this vasodilatation is accompanied by a striking *natriuresis*.[21] When the agent is given intravenously, however, an equally striking *antinatriuresis* occurs—presumably because of the blood pressure fall.[9,17,20]

The impact of these agents on renal blood supply and renal sodium handling when given systemically varies widely among individual patients, from a net increase to a net decrease in renal blood flow. However, antinatriuresis with sodium retention and, typically, a decrease in GFR occur, with even the most potent direct renal vasodilators in the series—hydralazine, diazoxide and minoxidil.[14–16,22,23] Thus, to date, selection of nonspecific vasodilators for the vasodilator action on the kidney has not spared the patient the negative renal influence of these agents.

Three new classes of agents have been developed that may have special implications for the kidney: calcium entry–blocking agents, converting enzyme inhibitors and dopamine analogs. Claims have been made that vasodilatation induced by calcium entry–blocking agents may be associated with less sodium retention.[24,25] However, rigorous evidence is not yet available, and the question remains controversial because the reports have involved small numbers of patients treated for a relatively short time. Calcium entry–blocking agents do provide an attractive potential. Diltiazem, 1 of the 3 calcium entry–blocking agents currently marketed in the United States, appears to have a special action on the renal blood supply, favoring a sustained or increased GFR and natriuresis despite the fall in arterial blood pressure.[26,27] The intriguing observation that normotensive offspring of hypertensive parents often show a potentiated renal vascular response to diltiazem[28] raises the interesting

possibility of a special renal action of this agent in essential hypertension.

The development of converting enzyme inhibitors provides a new approach to therapy and new tools for examining the underlying mechanisms of this disorder.[29] These agents are often effective even in severe hypertension, which has been resistant to standard triple therapy with a diuretic, hydralazine and a β-adrenergic blocking agent.[12] Recent studies suggest that this class of agents will exert an especially useful action on the kidney.[5,9] In patients with essential hypertension, the nonapeptide SQ 20881 induced a potentiated increase in renal blood flow[5] that was twice the increase in blood flow induced in normal subjects, despite a larger fall in blood pressure. Also, despite the fall in arterial blood pressure, SQ 20881 often induced an increase in GFR and, with it, natriuresis.[9] More recent studies performed with the orally effective analogs, captopril and enalapril, have shown a similar influence; the essential hypertensive patient enjoys a larger renal blood flow response and, despite the fall in arterial blood pressure, a well-maintained GFR.[31,32] Perhaps their influence on the kidney accounts for this class of agents' remarkable, often sustained impact on hypertension even in patients in whom traditional therapy has been ineffective.

The dopamine analogs, which are striking renal vasodilators in animal models,[32] have undergone too little study in man to allow any conclusion about their therapeutic potential.

What is the influence of antihypertensive agents on progression of renal microvascular abnormality to advanced nephrosclerosis and renal failure in hypertension? The impact of these agents is most evident when they are assessed in the treatment of severe hypertension already complicated by some degree of renal insufficiency. Three studies published in the past decade provide some insight and a relatively hopeful answer.[33–35] The 80 patients in the 3 studies were treated aggressively for prolonged periods. In each case, therapy for hypertension initially appeared to aggravate the already compromised renal function; however, with time and persistent lowering of the elevated arterial blood pressure, renal function usually improved, sometimes dramatically. In each study, a diuretic was used to reverse the sodium retention induced by dilators, and active vasodilators, especially hydralazine, methyldopa and oral diazoxide that were used for blood pressure control. In this population, in whom renal failure was the common mode of death—a 1-year mortality rate routinely exceeded 80% and was generally due to uremia—a striking improvement in natural history was obtained. One-year survival in the 3 series was 55, 76 and 80%—with stable or even improving renal excretory function.[33–35] Whether the newer vasodilators, calcium entry–blocking agents, converting enzyme inhibitors or dopamine analogs will produce an even more marked influence on natural history and renal function is not yet known.

In summary, the agents available to us for the treatment of hypertension have improved dramatically in the past decade and are likely to continue to improve over the next decade.[36] We have the luxury of being able to select our therapeutic objectives for the first time. Among the characteristics of new agents that are likely to be important, a salutary action on the kidney is high on the list.

Calcium Entry Blockers: Antihypertensive and Natriuretic Effects in Experimental Animals

TAKU NAGAO, PhD, ISAO YAMAGUCHI, BS, HIROSHI NARITA, PhD, and HIROMICHI NAKAJIMA, PhD

Hypotensive and natriuretic effects of calcium entry blockers were studied in spontaneously hypertensive rats (SHRs) and normotensive Wistar Kyoto rats (WKYs). In SHRs, the hypotensive action of diltiazem was enhanced, while that of hydralazine was not different from its action in WKYs. Diltiazem, unlike hydralazine and nifedipine, did not cause reflex tachycardia in rats. Diltiazem and nifedipine caused an increase in urine volume and sodium excretion. The natriuretic potency of diltiazem was the same in both SHRs and WKYs and was not affected by pretreatment with indomethacin. Diltiazem increased plasma renin activity but had no influence on plasma aldosterone concentration. Hydralazine increased both plasma renin activity and plasma aldosterone concentration and decreased sodium excretion.

In anesthetized dogs, diltiazem increased sodium excretion, glomerular filtration rate and renal blood flow. Diltiazem may have a direct effect on tubular sodium reabsorption. This assumption was supported by a study with short-circuit current of the isolated bullfrog bladder. It is likely that diltiazem's effect of increasing urine volume and sodium excretion is due mainly to changes in renal hemodynamics and partly to direct action on renal tubules. Diltiazem opposed angiotensin II-induced responses, such as renal vasoconstriction and reduction of glomerular filtration rate. Under this condition, a marked natriuretic effect was observed with both intravenous and intraarterial administration of diltiazem. The ability to increase urinary excretion of sodium is a desirable characteristic for an antihypertensive agent. Calcium entry blockers have this ability and are therefore able to act without causing sodium and water retention.

(Am J Cardiol 1985;56:56H–61H)

Calcium entry blockers were developed mainly as antianginal agents and recently have been established as useful antihypertensive agents.

Reflex tachycardia and sodium retention are the main adverse effects of antihypertensive vasodilators such as hydralazine and minoxidil.[1–4] With this in mind, several studies have examined the effects of various calcium entry blockers on renal function.[5–7] When administered directly into the renal artery of anesthetized dogs, calcium entry blockers produced increases in urine volume and urinary excretion of sodium. However, the effect on the glomerular filtration rate (GFR) differed among calcium entry blockers.

Diltiazem, a typical calcium entry blocker, was given the code number CRD-401 in its early stage of development. C, R and D represented the coronary, renal and dextro isomer components of the compound, respectively. In other words, the vasodilating action of the renal artery along with that of the coronary artery was noticed in the very early stages of development.

This article reports the antihypertensive and natriuretic effects of diltiazem in spontaneously hypertensive rats (SHRs) and its renal effects in anesthetized dogs.

Hypotensive Effects in Spontaneously Hypertensive Rats

Figure 1 shows the effects of diltiazem, hydralazine and nifedipine on blood pressure and heart rate in SHRs after oral administration. Blood pressure was measured by the tail-cuff method. As shown, all the drugs produced dose-dependent hypotensive actions. It is noteworthy, however, that hydralazine and nifedipine caused a marked increase in heart rate, whereas diltiazem showed a dose-related decrease.

In SHRs, a much higher dose of diltiazem than nifedipine was required to produce hypotension. However, in Grollman type 1-kidney renal hypertensive dogs, both drugs—orally and at the same doses (1 to 4

mg/kg)—caused hypotension to a similar extent.[8] The difference in the hypotensive doses of diltiazem between rats and dogs is considered to be due mainly to a difference in the metabolic pathway between the 2 animal species.[9,10] As shown in Figure 1, tachycardia induced by nifedipine was more marked than that caused by diltiazem. This indicates that reflex tachycardia is not a common feature of calcium entry blockers.

Figure 2 shows hypotensive actions of diltiazem and hydralazine in SHRs and normotensive Wistar Kyoto rats (WKYs) after oral administration. When changes in systolic blood pressure were expressed as percentages, hypotensive actions of hydralazine in SHRs did not significantly differ from those in WKYs. However, diltiazem showed a significantly stronger hypotensive action in SHRs than in WKYs.[11,12] The enhanced hypotensive action of diltiazem on hypertensive animals compared with normotensive control rats was also reported in deoxycorticosterone acetate-saline hypertensive rats[11,13] and in renal hypertensive rats.[12] Similar results were reported with nifedipine.[14] Therefore, hypotensive action seems to be a common characteristic of calcium entry blockers.

Natriuretic Effects in Spontaneously Hypertensive Rats and Wystar Kyoto Rats

Figure 3 shows the effects of diltiazem, hydralazine and nifedipine on urine volume and urinary excretion of sodium in SHRs. At doses causing a similar hypotensive action, diltiazem and nifedipine increased urine volume and sodium excretion in a dose-related manner. In contrast, hydralazine at a higher dose slightly increased urine volume but significantly decreased sodium excretion. This suggests that calcium entry blockers have different effects on renal function than those of such antihypertensive vasodilators as hydralazine.

We also examined the influences of orally administered diltiazem and hydralazine on plasma renin activity and plasma aldosterone concentration in SHRs. An arterial cannula was implanted in SHRs for blood sampling. Thirty minutes after drug administration, arterial blood was withdrawn from conscious subjects. Plasma renin activity and plasma aldosterone concentration were measured by radioimmunoassay. Hydral-

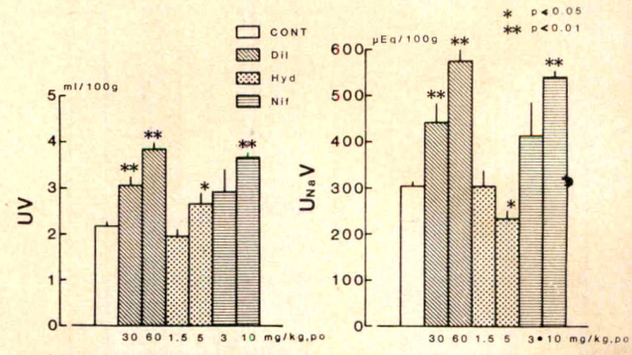

FIGURE 3. Effect of diltiazem (DIL), hydralazine (HYD) and nifedipine (NIF) on urine volume (UV) and urinary excretion of sodium ($U_{Na}V$) in saline-loaded spontaneously hypertensive rat. Physiologic saline (2.5 ml/100 g, body weight) was loaded twice at a 1-hour interval; urine was collected for 5 hours.

azine was shown to increase both plasma renin activity and aldosterone concentration; in contrast, diltiazem increased plasma renin activity without changing aldosterone concentration (Fig. 4).

No increase in plasma aldosterone concentration was reported with other calcium entry blockers.[15] In in vitro experiments, calcium entry blockers have been shown to inhibit angiotensin II-induced aldosterone release.[16–18] This may explain why calcium entry blockers produce no increase in plasma aldosterone concentration in conscious SHRs. In contrast, hydralazine increases plasma aldosterone concentration and may result in sodium retention.

In addition to the natriuretic effect of diltiazem after a single oral dose, we examined the effect of long-term treatment with diltiazem on body fluid distribution and plasma sodium concentration in SHRs.[12] Long-term administration of diltiazem (30 mg/kg day for 8 weeks) to young SHRs suppressed blood pressure

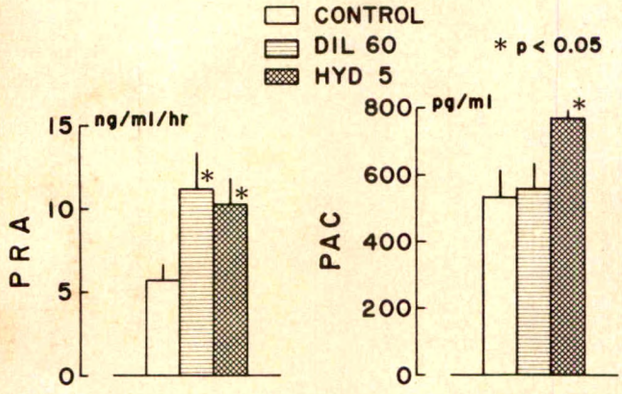

FIGURE 4. Influence of orally administered diltiazem (DIL) and hydralazine (HYD) on plasma renin activity (PRA) and plasma aldosterone concentration (PAC) in conscious spontaneously hypertensive rats. Each column and vertical bar represent the mean ± standard error of the 5 to 6 experiments.

significantly during the development and at the plateau levels of hypertension, and caused no changes in body fluid distribution and plasma sodium concentration. These results are comparable with previous findings: diltiazem does not increase plasma aldosterone concentration, and it produces a natriuretic effect.

Mechanism of the Natriuretic Effect

The natriuretic effect of diltiazem was also examined in WKYs. Figure 5 shows that oral diltiazem, 60 mg/kg, produced marked increases in urine volume and urinary excretion of sodium. These effects of diltiazem in WKYs were as potent as its effects in SHRs. On the other hand, as shown in Figure 2, the diltiazem-induced hypotensive action was more potent in SHRs than in WKYs, and thus renal hemodynamics could be affected markedly in SHRs. Therefore, the natriuretic effect of diltiazem cannot be explained entirely by renal hemodynamic effects.

As shown in Figure 5, indomethacin did not affect the diltiazem-induced natriuretic effect in WKYs. Urinary prostaglandin E_2 excretion was significantly increased with the increase in urine volume as measured by radioimmunoassay. Even under conditions in which the excretion of prostaglandin E_2 was completely suppressed by pretreatment with oral indomethacin, 10 mg/kg, the increasing effects of diltiazem on urine volume and sodium excretion were not influenced. These results suggest that prostaglandin is not involved in the natriuretic effect of diltiazem.

In anesthetized dogs, renal function was studied by the clearance method under mild saline loading, and renal blood flow was measured by an electromagnetic flowmeter. When diltiazem was infused into the renal artery at a rate of 10 to 30 μg/kg/min, renal blood flow, GFR, urine volume and sodium excretion increased markedly.[5] Thus the natriuretic effect of diltiazem may be caused by changes in renal hemodynamics and an increase in GFR. When the renal blood flow was

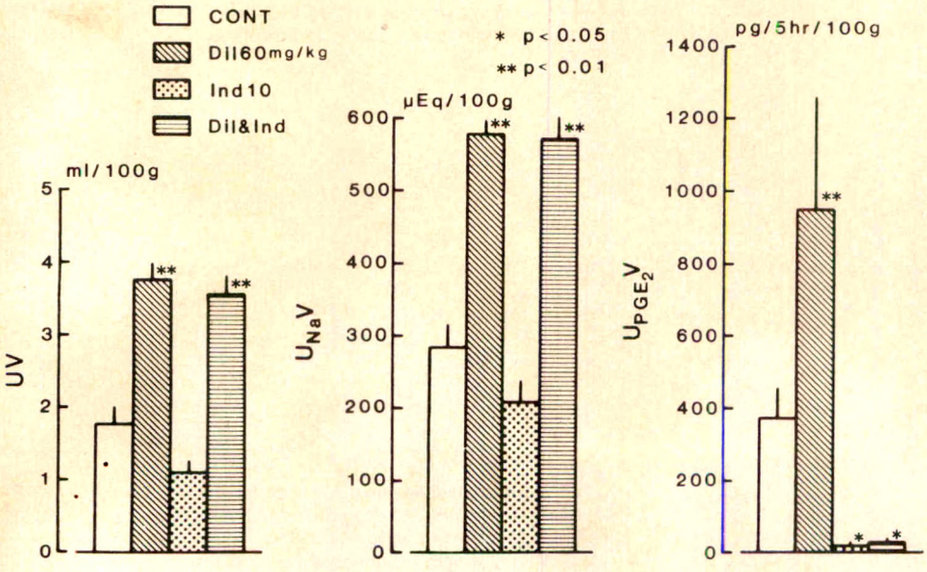

FIGURE 5. Natriuretic effect of diltiazem (DIL) in saline-loaded Wystar Kyoto rats in the presence and absence of indomethacin (IND.) Indomethacin was administered together with saline loading. Conditions of saline loading and urine collection were the same as those in Figure 3. Each column and vertical bar represent the mean ± standard error of 4 to 7 experiments.

kept constant with an aortic clamp during diltiazem infusion, sodium excretion was significantly increased but no change was observed in GFR and para-aminohippuric acid clearance.[5] The stopflow experiment under osmotic diuresis demonstrated that the sodium concentration of tubular fluid was elevated by diltiazem over the region corresponding to the distal segment of the nephron,[5] indicating that diltiazem suppressed the sodium reabsorption in the distal nephron. A similar result was also obtained by Abe et al.[19] Tsuchiya et al[20] studied the microautoradiographic distribution of carbon-14–labeled diltiazem in the dog kidney after renal arterial injection. They showed definite accumulation of radioactivity in the distal tubules that are involved in sodium transport. These results suggest that diltiazem-induced natriuresis is, at least in part, due to its direct action on renal tubules as well as to changes in the renal hemodynamics.

In the isolated bullfrog (*Rana catesbeiana*) urinary bladder, which is a model for the distal tubule, we assessed sodium transport by measuring short-circuit current using the method of Ussing and Zerahn[21] (Fig. 6). Diltiazem suppressed short-circuit current when applied to the serosal side. A weak but definite inhibition was observed when it was applied to the mucosal side. In this aspect, diltiazem contrasts with diuretics: hydrochlorothiazide and furosemide act selectively from the mucosal side, and ethacrynic acid acts selectively from the serosal side. These results support the hypothesis that the natriuretic effect of diltiazem is due to an inhibition of sodium reabsorption along the distal tubule as well.

Verapamil has been shown not to increase the GFR but is suggested to have a direct action on the renal tubule.[7,22] Inhibition by verapamil of short-circuit current has also been reported.[23] The natriuretic effect of nicardipine is explained by changes in renal hemodynamics and an increase in GFR.[6] Recently, the calcium entry blocker felodipine has been shown to inhibit sodium reabsorption at distal tubules using the micropuncture method in rats.[24]

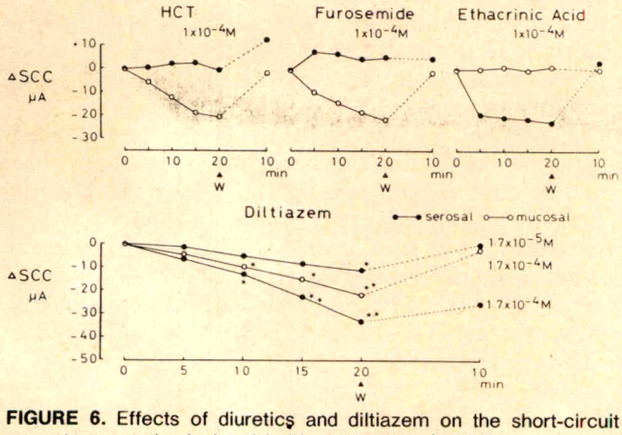

FIGURE 6. Effects of diuretics and diltiazem on the short-circuit current across the isolated bullfrog bladder. Δ SCC = change in short-circuit current; HCT = hydrochlorothiazide; W = wash. Each point represents: for diuretics, the mean of 3 experiments; for diltiazem, 1.7×10^{-5} *M*, the mean of 9 experiments; for diltiazem, 1.7×10^{-4} *M* (mucosal), the mean of 6 experiments; for diltiazem, 1.7×10^{-4} *M* (serosal), the mean of 8 experiments. Cord conductance was not changed for application of diltiazem or diuretics. * $p < 0.05$, ** $p < 0.01$ versus preadministration level.

Interaction with Angiotensin II

In anesthetized dogs, the vasodilating effect of diltiazem on renal vasculature when constricted by angiotensin II was more marked than when it was constricted by epinephrine.[5] Figure 7 shows the effect of intravenous administration of diltiazem on renal blood flow, urine volume and urinary excretion of electrolytes in anesthetized dogs with and without angiotensin II loading. Under the angiotensin II-unloaded condition, diltiazem tended to increase urine volume and sodium excretion when administered intravenously to dogs. However, diltiazem produced marked increases in urine volume and sodium excretion under the angiotensin II-loaded condition in which renal vas-

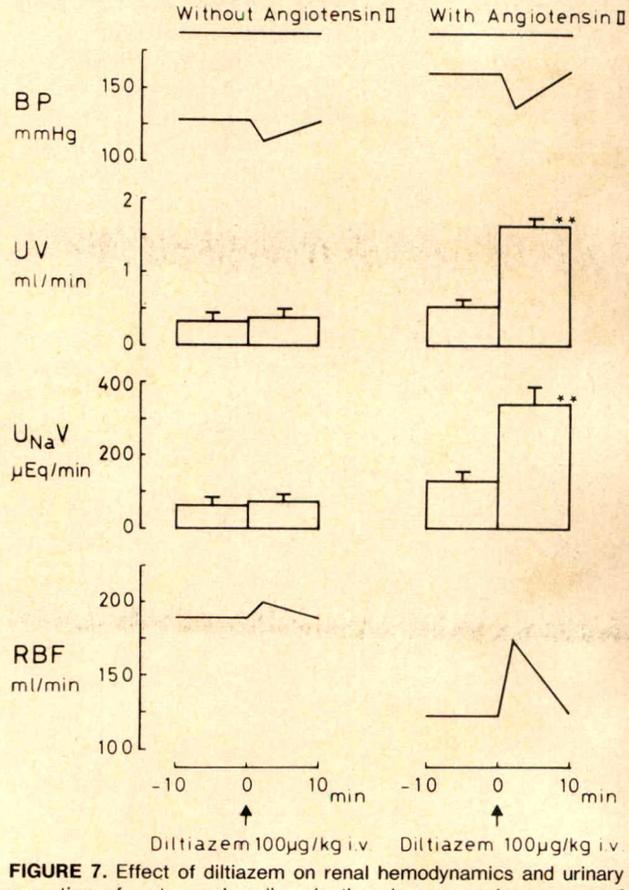

FIGURE 7. Effect of diltiazem on renal hemodynamics and urinary excretion of water and sodium in the absence and presence of angiotensin II loading in anesthetized dogs. Angiotensin II was infused intravenously at the dose of 0.25 μg/kg/min. Diltiazem was administered after urine flow became constant. BP = blood pressure; RBF = renal blood flow; UV = urinary volume; $U_{Na}V$ = urinary sodium excretion. Each column and vertical bar represent the mean ± standard error of 6 experiments. Blood pressure and renal blood flow are depicted as mean changes. Urine volume and urinary sodium excretion were determined by collecting urine for 10 minutes. ** $p < 0.01$ versus control.

cular resistance was doubled. The effect of diltiazem by intraarterial infusion on renal function was then studied using the clearance method. As shown in Figure 8, angiotensin II caused marked decreases in renal blood flow and GFR. Diltiazem caused increases in renal blood flow and GFR to levels higher than those before angiotensin II loading, and urine volume and sodium excretion were increased remarkably. In short, diltiazem noticeably improved renal function under conditions in which renal vascular resistance was elevated by angiotensin II.

Recently, glomerular mesangial cells have been studied as angiotensin II receptors regulating GFR.[25–27] Diltiazem inhibited contraction induced by angiotensin II in cultured mesangial cells.[28] As mentioned previously, diltiazem showed inhibitory effects on angiotensin II-induced responses in the renal vascular bed as well as reduction of GFR. It is possible that the increase in GFR by diltiazem results from the reduction of angiotensin II-induced contractions of renal vasculature and/or mesangial cells.

In summary, hypotensive and natriuretic effects of calcium entry blockers were studied in SHRs and WKYs. The hypotensive effects of diltiazem were more pronounced in SHRs than in WKYs, while hydralazine showed almost the same hypotensive activity in the 2 groups. This enhanced hypotensive action on hypertensive animals seems to be a common feature of calcium entry blockers. Diltiazem, unlike nifedipine or hydralazine, did not cause reflex tachycardia in either strain. In addition, diltiazem had no influence on plasma aldosterone concentration, although plasma renin activity was increased by the compound. On the other hand, both diltiazem and nifedipine at the same hypotensive doses increased urine volume and urinary excretion of sodium. The natriuretic effect of diltiazem was not affected by indomethacin, suggesting that prostaglandin is not involved in the natriuretic action of diltiazem. It was also found that long-term administration of diltiazem to young SHRs caused no change in body fluid distribution and plasma sodium concentration. In contrast to the effects of diltiazem, hydralazine decreased urinary sodium excretion and increased plasma aldosterone concentration. Plasma renin activity was also increased by hydralazine. It was shown that diltiazem is an antihypertensive agent with an enchanced hypotensive action in hypertensive subjects and does not cause tachycardia and sodium retention. Unlike hydralazine, diltiazem may not be associated with a decrease in antihypertensive activity during long-term treatment.

The effect of diltiazem on renal function was studied in anesthetized dogs. Diltiazem by intraarterial administration increased sodium excretion, GFR and renal blood flow. Therefore, changes in renal hemodynamics were likely to be responsible for the natriuretic effect of diltiazem. However, aortic clamp and stop-flow experiments suggested that diltiazem suppressed sodium reabsorption in the distal part of the nephron. The effect was supported by a study on short-circuit current applied to an isolated bladder preparation. It can be said that diltiazem's effect of increasing urine volume and urinary sodium excretion is due mainly to renal hemodynamics and partly to direct action on renal tubules. Diltiazem opposed angiotensin II-induced responses, such as renal vasoconstriction and reduction of GFR. In addition, under angiotensin II-loaded conditions, a remarkable natriuretic effect was observed after intravenous and intraarterial administration of diltiazem. This suggests that diltiazem improves renal hypofunction with an increase of mesangial cells. It also suggests that diltiazem is useful for the treatment of hypertension with increased renal vascular resistance.

Calcium entry blockers generally showed enhanced hypotensive effect in the hypertensive state, but induction of reflex tachycardia is not a common feature. The ability of calcium entry blockers to increase urinary excretion of sodium is a desirable characteristic for an antihypertensive agent. However, to what extent these natriuretic properties are involved in the antihypertensive effects should be examined for each calcium entry blocker.

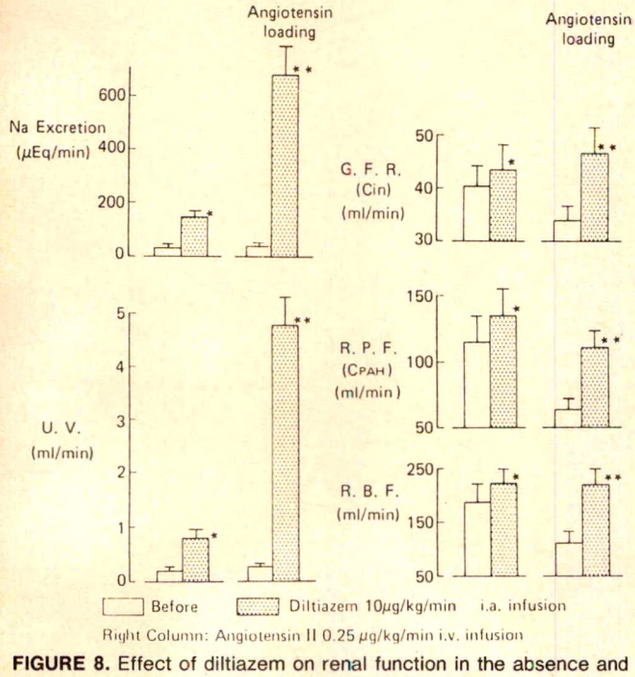

FIGURE 8. Effect of diltiazem on renal function in the absence and presence of angiotensin II loading in anesthetized dogs. Na = sodium; UV = urinary volume; GFR = glomerular filtration rate (insulin clearance); RPF = renal plasma flow (*p*-aminohippuric acid clearance); RBF = renal blood flow. Each column and vertical bar represent the mean ± standard error of 6 experiments. * $p < 0.05$, ** $p < 0.01$ versus before.

Effects of Calcium Entry Blockers on Renin-Angiotensin-Aldosterone System, Renal Function and Hemodynamics, Salt and Water Excretion and Body Fluid Composition

JOHN H. BAUER, MD, SOBHA SUNDERRAJAN, MD, and GARRY REAMS, MD

The renal effects of the calcium entry–blocking drugs diltiazem, nifedipine, verapamil and nitrendipine are reviewed. Although nifedipine stimulates plasma renin activity on a short-term basis, none of the calcium entry blockers produces a clinically significant sustained effect on any of the components of the renin-angiotensin-aldosterone system. Although all of the calcium entry blockers effectively lower blood pressure, none adversely affects renal function; glomerular filtration rate and effective renal plasma flow are maintained. Diltiazem may increase glomerular filtration rate via attenuation of the intrarenal effects of angiotensin II or norepinephrine. Although diltiazem and nifedipine increase salt and water excretion on a short-term basis, none of the calcium entry blockers produces a clinically significant sustained effect on salt and water excretion; serum electrolytes, urinary sodium and potassium excretion, body fluid composition and body weight are unchanged. Thus, calcium entry blockers can be expected to assume a prominent role in the treatment of hypertension because of their ability to lower blood pressure while preserving renal perfusion and function.

(Am J Cardiol 1985;56:62H–67H)

Although the calcium entry blockers were initially characterized by their pharmacologic ability to produce coronary vasodilation with myocardial depression, it has become clear that the individual members of this family of drugs differ not only in their pharmacokinetic properties, but also in their pharmacodynamic effects. Specifically, individual calcium entry blockers differ in regard to their effects on the myocardium (pacemaker activity, atrioventricular conduction, myocardial contractility), excitation-contraction coupling of smooth muscle (coronary, renal and peripheral vasculature) and stimulus-secretion coupling (juxtaglomerular cell renin secretion).

A large number of calcium entry–blocking drugs are currently undergoing clinical investigation, but only 4 drugs—diltiazem, nifedipine, verapamil and nitrendipine—have been studied sufficiently to permit some clinical individuation of their renal effects. Each of these 4 calcium entry–blocking drugs will be reviewed in terms of its known effects, both short- (response to an initial dose) and long-term, on the renin-angiotensin-aldosterone system, renal function and hemodynamics, salt and water excretion and body fluid composition.

Renin-Angiotensin-Aldosterone System (Table I)

Diltiazem: Neither the intravenous administration of diltiazem nor its short-term oral administration (60 to 90 mg) produces a significant effect on recumbent plasma renin activity.[1–3] Long-term oral therapy (180 to 360 mg/day for 8 weeks) also has no consistent effect on recumbent plasma renin activity.[2–4] It is presumed that diltiazem has no effect on the circulating level of angiotensin II; however, the systemic vasoconstricting action of exogenously administered angiotensin II is significantly suppressed by the concurrent infusion of diltiazem.[1,3,5,6] The intravenous administration of diltiazem produces no significant effect on recumbent plasma aldosterone concentration.[1] We have observed that long-term oral diltiazem therapy (240 to 480 mg/day administered for 8 weeks to 17 hypertensive patients) has no significant effect on recumbent plasma aldosterone concentration: plasma aldosterone concentration was 6.2 ng/dl after both placebo and diltiazem therapy.

TABLE I Effects of Calcium Entry–Blocking Agents on the Renin-Angiotensin-Aldosterone System

	PRA	Angiotensin II	Aldosterone	Vascular Reactivity AII
Short-term				
Diltiazem	No Δ	No Δ	No Δ	Attenuation
Nifedipine	↑	↑	No Δ	Attenuation
Verapamil	No Δ	. . .	. . .	Attenuation
Nitrendipine	No Δ	. . .	. . .	. . .
Long-term				
Diltiazem	No Δ	. . .	No Δ	. . .
Nifedipine	No Δ	. . .	No Δ	No Δ
Verapamil	No Δ	. . .	No Δ	. . .
Nitrendipine	No Δ	. . .	No Δ	No Δ

Aldosterone = plasma aldosterone concentration; angiotensin II = plasma angiotensin II concentration; PRA = plasma renin activity; vascular reactivity AII = systemic vascular (blood pressure) response to exogenously administered angiotensin II during concurrent calcium entry–blocker therapy.

TABLE II Effects of Calcium Entry Blockers on Renal Function and Hemodynamics

	GFR	ERPF	RVR	Intrarenal Effects of AII
Short-term				
Diltiazem	No Δ ↑	No Δ ↑	. . .	Attenuation
Nifedipine	No Δ	No Δ	. . .	. . .
Verapamil	No Δ	. . .	. . .	Attenuation
Nitrendipine	. . .	. . .	. . .	. . .
Long-term				
Diltiazem	No Δ ↑	No Δ ↑	No Δ ↓	. . .
Nifedipine	No Δ	No Δ	. . .	. . .
Verapamil	No Δ	. . .	. . .	. . .
Nitrendipine	No Δ	. . .	. . .	. . .

ERPF = effective renal plasma flow; GFR = glomerular filtration rate; intrarenal effects of AII = GFR or ERPF response to exogenously administered angiotensin II during concurrent calcium entry–blocker therapy; RVR = renal vascular resistance.

Nifedipine: The short-term sublingual or oral adminstration of nifedipine (10 to 30 mg) to normotensive subjects or hypertensive patients produces a significant increase in plasma renin activity;[7–12] the effect peaks at 1 to 2 hours, returning to control levels at 4 hours.[7,10,11] This increase has been shown to be directly correlated with pretreatment plasma renin activity values[8,11] and inversely correlated with age.[9] However, long-term oral therapy (30 to 80 mg/day for up to 3 weeks) has no consistent effect on plasma renin activity.[8,12,13] The short-term oral administration of nifedipine significantly increases plasma angiotensin II concentration.[9] Nevertheless, neither short- nor long-term administration of nifedipine has an effect on plasma aldosterone concentration.[8,9,13] Although short-term intravenous administration of nifedipine to normotensive subjects has been reported to decrease significantly the pressor effect of exogenously administered angiotensin II,[14] long-term oral therapy (30 to 60 mg/day for 2 weeks) has no effect on the vasoconstrictor action of exogenously administered angiotensin II.[15,16]

Verapamil: Although the intravenous administration of verapamil to normotensive subjects increases plasma renin activity,[3] short-term oral administration (160 mg) produces no consistent effect.[10] Similar results have been reported in hypertensive patients after long-term administration of verapamil in dosages up to 480 mg/day for as long as 4 months.[13,17,18] However, the systemic vasoconstrictor action of exogenously administered angiotensin II is significantly suppressed by the concurrent infusion of verapamil.[3] Long-term oral administration of verapamil (240 mg/day) has no consistent effect on plasma aldosterone concentration.[13]

Nitrendipine: The short-term oral administration of nitrendipine (20 mg) to hypertensive patients has been reported to have no effect on plasma renin activity;[19] similar results have been reported after long-term therapy at dosges of up to 40 mg/day for 5 weeks.[20] Moreover, long-term nitrendipine administration does not attenuate pressor responses to exogenously infused angiotensin II.[20] Nitrendipine appears to have no effect on plasma aldosterone concentrations.[20]

Renal Function and Hemodynamics (Table II)

Diltiazem: The short-term oral administration of diltiazem (30 to 60 mg) to patients with existing arteriosclerotic cardiovascular disease (with or without hypertension) has been reported to have no consistent effect on either glomerular filtration rate (GFR) as measured by iodine-131 iothalamate or effective renal plasma flow as measured by I-131 hippuran, 3 hours postdosing.[21] A similar study in patients with chronic congestive heart failure showed no consistent effect on either GFR or effective renal plasma flow.[22] Studies in patients with primary or secondary renal disease have suggested that long-term oral diltiazem therapy (at dosages ranging from 30 to 120 mg/day from 1 week to 3 months) tended to increase GFR and effective renal plasma flow, the latter demonstrating the greater and more consistent change.[5,23–25] We studied 17 essential

TABLE III Effects of Diltiazem on Renal Function and Hemodynamics

† $p < 0.01$.
†† $p < 0.025$.
ERPF = effective renal plasma flow by para-aminohippurate; filt fract = filtration fraction = GFR/ERPF × 100; GFR = glomerular filtration rate by inulin clearance; MAP = mean arterial pressure = diastolic pressure + one-third pulse pressure; RBF = renal blood flow = ERPF/0.74/(1-Hct); RVR = renal vascular resistance = (MAP/RBF) × 80,000; SEM = standard error of the mean.

hypertensive patients receiving 240 to 480 mg/day of diltiazem for 8 weeks. Although mean arterial pressure decreased from 122 to 108 mm Hg, renal function and hemodynamics were not significantly altered (Table III). However, in 8 patients initially exhibiting a pretreatment GFR ≤80 ml/min/1.73 m^2, there was a marked increase (48%) in the rate (Table IV). Further, effective renal plasma flow and renal blood flow were increased, and renal vascular resistance was decreased. Short-term studies in animals, after either the intraarterial (renal) or intravenous infusion of diltiazem, have demonstrated diltiazem-induced dose-dependent increases in GFR and effective renal plasma flow.[26–29] Further, decreases in effective renal plasma flow induced by exogenously administered angiotensin II can be attenuated by concurrently administering diltiazem.[5,25,27]

Nifedipine: The short-term intravenous administration of nifedipine (1 mg) to patients with essential or renovascular hypertension has been reported to have no significant effect on either GFR as measured by inulin clearance or effective renal plasma flow as measured by p-aminohippurate clearance.[30] Similar results have been reported after the short-term oral administration of nifedipine (10 mg)[10,31] and after its more prolonged administration (40 mg/day for 1 to 3 weeks).[32,33] A recent report, however, has suggested that nifedipine may cause acute, reversible deterioration in renal function in patients with preexisting renal insufficiency.[34]

Verapamil: The short-term oral administration of verapamil (160 mg) has been reported to have no effect on creatinine clearance in either normotensive subjects or hypertensive patients.[10] Similar results have been reported after the long-term administration of verapamil in dosages ranging up to 480 mg/day for as long as 12 months.[17,18] Animal experiments, however, suggest that verapamil can reverse exogenous angiotensin II–mediated changes in the renal cortical microcirculation.[35] Specifically, verapamil inhibited angiotensin II–induced decreases in both the capillary plasma flow (mediated by efferent arteriolar vasocon-

TABLE V Effects of Calcium Entry Blockers on Salt and Water Excretion and Body Fluid Composition

striction) and the ultrafiltration coefficient (mediated by mesangial contraction). These results suggest that calcium may be an important cofactor required for the expression of the intrarenal actions of angiotensin II.

Nitrendipine: Long-term oral nitrendipine therapy (10 to 40 mg/day for 5 weeks) has been reported to have no effect on the creatinine clearance of essential hypertensive patients.[20]

Salt and Water Excretion and Body Fluid Composition (Table V)

Diltiazem: The short-term oral administration of diltiazem (30 to 60 mg) to patients with either existing arteriosclerotic cardiovascular disease or chronic congestive heart failure has been reported to increase urinary sodium excretion, with the peak effect occurring 2 to 3 hours after dosing;[21,22] however, diltiazem had no effect on urinary potassium excretion. In patients with primary or secondary renal disease, the intravenous administration of diltiazem (10 to 40 mg over 10 minutes to 2 hours) has been reported to increase both urine flow rate and urinary sodium excretion.[25,36] However, the long-term oral administration of diltiazem, in dosages ranging up to 360 mg/day, has not been associated with changes in serum electrolytes or fluid retention as evidenced by edema or weight gain.[4,37] We have observed that long-term oral diltiazem therapy (240 to 480 mg/day for 8 weeks) administered to 17 hypertensive patients has no effect on serum electrolytes, body fluid composition or body weight (Table VI); further, long-term diltiazem therapy had no effect on salt and water excretion (Table VII).

A short-term study in dogs showed that the renal arterial infusion of diltiazem produces a prompt increase in urine flow, sodium excretion, osmolar clearance and free water clearance.[26] Yamaguchi et al[26] suggested that diltiazem has a direct effect on tubular sodium reabsorption because natriuresis could be maintained under conditions that prevented a drug-induced increase in effective renal plasma flow. A short-term study in rats demonstrated that diltiazem (30 to 60 mg/kg administered orally) significantly increased urine volume and urinary excretion of both sodium and potassium in a dose-related manner.[38] However, repeated oral administration (30 mg/kg/day for 8 weeks) had no effect on plasma sodium or potassium concentration, total body water, extracellular fluid or plasma volume, suggesting that diltiazem did not cause sodium or water retention.

TABLE VI Effects of Diltiazem on Body Fluid Composition and Weight

	Placebo (4 weeks, n = 17)	Diltiazem (8 weeks, n = 17)
RCM (liter) Mean ± SEM	2.0 ± 0.2	2.1 ± 0.2

TBV (liter) Mean ± SEM	5.5 ± 0.5	5.5 ± 0.5
ECF (liter) Mean ± SEM	18.4 ± 1.4	18.9 ± 1.4
TBW (liter) Mean ± SEM	48.5 ± 3.4	46.5 ± 4.4
WT (kg) Mean ± SEM	89.5 ± 3.4	89.1 ± 3.4

ECF = extracellular fluid by $Na_2\ ^{35}SO_4$; PV = plasma volume by I-125 HSA; RCM = red cell mass by Cr-51 RBC; TBV = total blood volume = RCM + PV; TBW = total body water by ^3H_2O; WT = weight.

TABLE VII Effects of Diltiazem on Salt and Water Excretion

	Placebo (4 weeks, n = 17)	Diltiazem (8 weeks, n = 17)
$U_{Na}V$ (mEq/g creat) Mean ± SEM	115 ± 8	99 ± 12
U_KV (mEq/g creat) Mean ± SEM	38 ± 5	40 ± 6
FE_{Na} (%) Mean ± SEM	1.7 ± 0.3	1.1 ± 0.2
FE_K (%) Mean ± SEM	11.5 ± 1.9	11.3 ± 1.9
V (ml/min) Mean ± SEM	10.3 ± 1.5	10.8 ± 1.2
C_{H_2O} (ml/min/1.73 m^2) Mean ± SEM	7.4 ± 1.2	6.7 ± 1.1

C_{H_2O} = free water clearance; FE_K = fractional potassium excretion × 100; FE_{Na} = fractional sodium excretion × 100; U_KV = 24-hour urinary potassium excretion; $U_{Na}V$ = 24-hour urinary sodium excretion; V = urinary flow rate.

Nifedipine: The acute intravenous administration of nifedipine (1 mg) to patients with essential and renovascular hypertension was reported to increase urine flow rate and sodium clearance.[30] Similar results have been reported after short-term oral administration of nifedipine (10 mg);[10] there was no effect on potassium excretion. Long-term studies, however, do not support sustained diuretic or natriuretic effects. Long-term nifedipine therapy (in dosages ranging up to 60 mg/day) does not significantly alter serum or urinary electrolytes,[16,32,39] plasma volume[12,13] or body weight.[13,16,32,33,40]

Verapamil: Neither short-term oral administration of verapamil (160 mg)[10] nor long-term oral therapy (dosages ranging up to 480 mg/day for as long as 2 weeks)[18] has an effect on urinary flow rate or sodium or potassium excretion in either normotensive subjects or hypertensive patients. Further, long-term verapamil therapy is not associated with significant changes in serum electrolytes,[35] plasma volume[13] or body weight.[13,40,41]

Nitrendipine: Long-term oral nitrendipine therapy (10 to 40 mg/day for 5 weeks) has no significant effect on urinary excretion of sodium or potassium.[20]

Conclusions

Renin-angiotensin-aldosterone system: Because calcium may inhibit renin secretion by a direct action on the juxtaglomerular cell,[42] the administration of a calcium entry–blocking drug might be expected to stimulate renin secretion. However, only nifedipine, the most potent peripheral vasodilator of the drugs studied, consistently produces this effect; and it does this only after short-term administration. None of the other calcium entry–blocking drugs produces a clinically significant alteration, after long-term administration, in any of the components of the renin-angiotensin-aldosterone system. Although the acute systemic vasoconstricting action of exogenously administered angiotensin II is attenuated by a concurrent infusion of diltiazem, nifedipine or verapamil —presumably by decreasing the sensitivity of the vasculature to angiotensin II by preventing an increase in cytosol-ionized calcium—this effect is lost after the long-term administration of either nifedipine or nitrendipine. Thus, calcium entry blockers appear to have little or no influence on the renin-angiotensin-aldosterone system as it relates to systemic blood pressure control.

Renin function and hemodynamics: Among the calcium entry–blocking drugs currently under study, only diltiazem has been shown to increase GFR or effective renal plasma flow and to decrease renal vascular resistance. None of these calcium entry–blocking drugs adversely affects renal function or hemodynamics. There are at least 2 potential mechanisms for the observed increase in GFR or effective renal plasma flow after diltiazem therapy: reversal of angiotensin II–induced vasoconstriction (mesangium or efferent arteriolar tone) and reversal of norepinephrine-induced vasoconstriction (mesangium or efferent arteriolar tone). The nonspecific effect of calcium entry blockers to prevent an increase in cytosol-ionized calcium would be expected to decrease the sensitivity of the renal vasculature and the mesangium to both angiotensin II and norepinephrine. Indeed, several investigators have demonstrated that diltiazem and verapamil attenuate the intrarenal effects of both exogenously administered angiotensin II[5,26,27,35] and norepinephrine.[43] In addition, diltiazem and verapamil have been shown to differentially affect α-adrenergic receptors. Both drugs preferentially antagonized postsynaptic (voltage-activated calcium channel) α_2-adrenergic receptors.[44–46] Diltiazem and verapamil selectively interfere with the vasoconstrictor action of norepinephrine on the afferent arteriole (suggesting a greater density of α_2 receptors), while leaving intact its action on the efferent arteriole (suggesting a greater density of α_1-adrenergic receptors).[43] Our observation that GFR increased in hypertensive patients, when initially impaired, without an associated increase in the filtration fraction, supports the differential effect of norepinephrine on the renal vasculature, but does not exclude the possibility of a reversal of a direct angiotensin II or norepinephrine effect on the glomerulus (mesangium). Reversal of angiotensin II-mediated–efferent arteriolar vasoconstriction would have been expected to disproportionately enhance effective renal plasma flow, decreasing the filtration fraction.

Salt and water excretion and body fluid composition: Activation of renal α_2 adrenoceptors increases renal retention of sodium and water (this is mediated by inhibition of adenylate cyclase; reducing cyclic adenosine monophosphate diminishes the flux of sodium and water through the wall of the proximal tubule in the lumen).[47,48] Thus, antagonism of renal α_2-adrenergic receptors by a calcium entry–blocking drug might be expected to enhance sodium and water excretion. However, only diltiazem and nifedipine have been shown to induce natriuresis and diuresis on a short-term basis. More important, none of these calcium entry–blocking drugs was shown to have a clinically important sustained effect on salt and water excretion. This conclusion is supported by the absence of an observed effect of calcium entry blockers on serum electrolytes, body fluid composition or body weight. However, anecdotal case reports do attest to the potential for these drugs to produce edema. The frequency or mechanism for this potential adverse effect is unclear. Because the calcium entry–blocking agents generally lower blood pressure without producing salt and water retention, these drugs can be expected to assume a prominent role as first-step therapy in the treatment of patients with hypertensive diseases.

Renin, Calcium Metabolism and the Pathophysiologic Basis of Antihypertensive Therapy

LAWRENCE M. RESNICK, MD, and JOHN H. LARAGH, MD

The renin-angiotensin-aldosterone system regulates blood pressure and volume homeostasis in addition to sodium and potassium metabolism, and may be linked to divalent cation metabolism as well as hypertensive disease. In essential hypertension, circulating serum magnesium and Ca^{++}, and the calcium regulating hormones, parathyroid hormone, calcitonin and 1,25 dihydroxyvitamin (1,25D) are different in the various renin subgroups. Elevated blood pressure induced by such maneuvers as dietary salt loading is associated with exacerbations of these calcium metabolic deviations, and appears related to salt-induced changes in serum Ca^{++} or 1,25D levels. Short- or longer-term lowering of blood pressure with the calcium-channel blocker, nifedipine, or with calcium or magnesium supplementation is associated with a shift of renin system activity and calcium metabolic indexes back to average normotensive values in those subjects most susceptible to these hypotensive agents.

These observations suggest that deviations in calcium metabolism in essential hypertension may be related to the pathophysiology of the hypertensive process. Further, renin system activity and calcium metabolic indexes such as serum Ca^{++} levels may help target specific subgroups of hypertensive populations most susceptible to various dietary or drug maneuvers, and thus may provide a basis to better understand and treat clinical hypertension.

(Am J Cardiol 1985;56:68H–74H)

Increased blood pressure is an abnormal physical sign that we appreciate as varying quantitatively in degree; however, we have often mistakenly considered it qualitatively as a single homogeneous entity. It is not. Our present knowledge of hypertension, the spectrum of biochemical and hormonal parameters contributing to hypertension and the varying clinical responses to therapeutic maneuvers all testify to the heterogeneity of hypertension. Thus, it would appear most reasonable to attempt therapeutic intervention on the basis of our ability to analyze the pathophysiology of hypertension for an individual patient. Assessment of the renin-angiotensin-aldosterone system by simple blood and urine measurements makes this effort realistic and practical, and we have used it for over a decade.

We will review how the renin system operates physiologically as a vasoconstriction-volume control system, consider evidence for the clinical and biochemical heterogeneity of hypertension based on analysis of renin-sodium profiling and, finally, suggest how knowledge of renin system activity provides a rational basis for therapeutic choices in hypertension. This approach not only highlights the relevance of renin activity to hypertension, but also, interestingly, establishes a basis for understanding the contribution of calcium metabolism to the pathogenesis and therapy of hypertensive disease.

The renin-angiotensin-aldosterone system and vasoconstriction-volume analysis of blood pressure regulation: Renin was initially identified over 85 years ago as a pressor substance obtained from saline extracts of rabbit kidney,[1] but its relevance was not commonly appreciated until the classic experiments of Goldblatt et al,[2] who established renin as a humoral substance capable of causing hypertensive disease. Thereafter, renin was identified as an enzyme initiating a biochemical cascade that also involved angiotensin converting enzyme, and resulted in the formation of angiotensin II as an active effector molecule.[3,4] The connection of this biochemical cascade to potassium and sodium-volume homeostasis was advanced by Laragh and others who established that adrenal aldosterone production was chiefly regulated by angiotensin II,[5] as well as by potassium.[6] While further advances in our knowledge of the renin-aldosterone system continue, the system as it functions in the peripheral circulation has been defined (Fig. 1).[7]

Renal renin secretion is stimulated by a variety of hemodynamic, hormonal and ionic signals associated with decreased "effective" circulating blood volume, decreased blood pressure or other stress responses.[7] Increased circulating active renin (plasma renin activity) catalyzes the hydrolysis of plasma renin substrate, a protein of liver origin. This results in increased formation of angiotensin I, the C-terminal 10 amino acid fragment of plasma renin substrate. Angiotensin converting enzyme acts on angiotensin I by hydrolyzing the distal 2 amino acids to produce the 8 amino acid peptide, angiotensin II. Although the angiotensin converting enzyme is present in all vascular endothelial cells, most circulating angiotensin II is produced within the pulmonary vascular bed.[8] Angiotensin II acts directly as a vasoconstrictor to increase blood pressure, an effect magnified by its ability to release catecholamines in the periphery. A longer-term effect of angiotensin II is its ability to stimulate adrenal aldosterone production, which, in the presence of sufficient dietary sodium, causes renal sodium retention, increased pressor sensitivity to angiotensin II, volume expansion and/or increased blood pressure. Thus, the original signals for renin release are dampened by increased pressure or volume retention, suppressing renin secretion and operating as a classic negative feedback system (Fig. 1). Concurrent effects on potassium metabolism are regulated at the renal level, preventing abnormalities of volume or pressure from resulting in abnormal potassium metabolism.[9]

On the basis of these considerations, blood pressure may be considered to be dependent on 2 types of factors. Vasoconstrictor factors affect pressure by changing the tone of the blood vessel wall, altering internal vessel diameter and thus pressure. Volume factors alter the amount of circulating fluid present for any given amount of vasoconstrictor tone, and thus also directly affect pressure. Normally these 2 types of factors are balanced in see-saw fashion to maintain normal blood pressure and tissue perfusion under a variety of dietary and environmental circumstances. Indeed, there is a characteristic inverse, hyperbolic relation between circulating plasma renin activity and urinary sodium excretion, reflecting dietary sodium intake (Fig. 2). This relation, by defining the normal

Hi-RH (n = 11)	292 ± 37	84.3 ± 3.9*‡	44.1 ± 4.9‡

* $p < 0.05$ versus NI-BP.
† $p < 0.005$ versus NI-BP.
‡ $p < 0.001$ versus Lo-RH.
PTH = parathyroid hormone; CT = calcitonin; 1,25D = 1,25 dihydroxyvitamin D; NI-BP = normotensive control subjects; Lo-RH = low renin hypertensives; NI-RH = normal renin hypertensives; Hi-RH = high renin hypertensives.

link between sodium-volume and constrictor factors regulating volume-pressure homeostasis in man, provides valuable clues and a clinically practical approach to hypertensive disease.

The Hormonal and Biochemical Heterogeneity of Hypertension

Renin profiling in hypertension: If the same type of analysis, comparing plasma renin activity with ambient 24-hour sodium excretion, is attempted for subjects with essential hypertension, certain hypertensive subjects demonstrate an inappropriate excess of renin activity at levels of urinary sodium excretion normally associated with inhibition of renin secretion. On the other hand, another, larger group of hypertensive subjects—approximately 30%—have suppressed levels of plasma renin activity, even when, at a low urinary sodium excretion, one would expect a stimulation of renin secretion (Fig. 3). These deviations of plasma renin activity at a given level of urine sodium excretion from the tight correlation observed in normotensive subjects serve as the basis for "renin profiling," and define "high renin" and "low renin" essential hypertension as opposite clinical subgroups. In high renin hypertension, the excess pressure is usually renin dependent, while in low renin states, the renin system acts as if an excess of volume factors are present, not dependent on renin activity.[7]

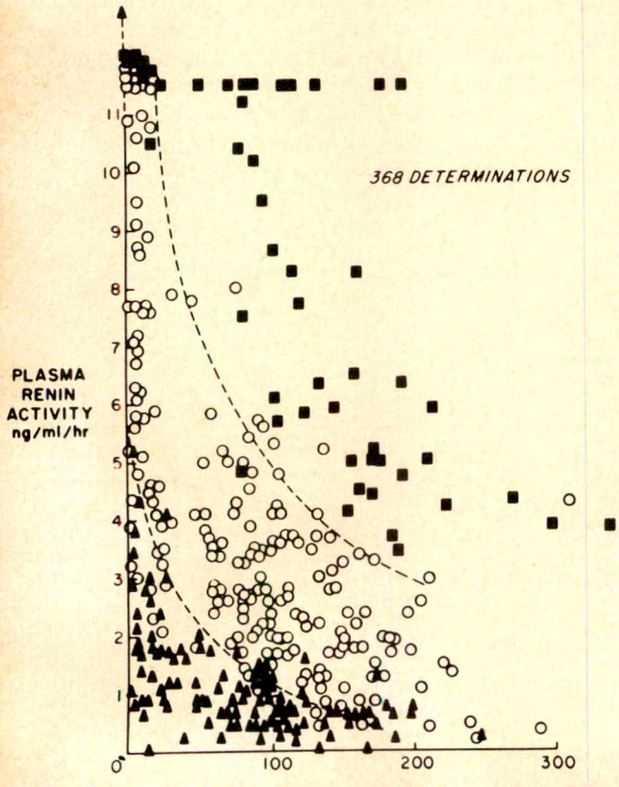

FIGURE 3. Relation of plasma renin activity to 24-hour urinary sodium excretion in hypertensive subjects. Dashed lines represent limits of plasma renin activity values for normotensive subjects at a given level of urinary sodium. (▲, ○ and ■ define low, normal and high renin hypertensives, respectively.)

Abnormalities of calcium metabolism in hypertension: While calcium has long been linked to the molecular events of muscle contraction, abnormalities of calcium metabolism in hypertensive disease have only recently been appreciated.[10] Further, no coherent picture has emerged of the specific manner in which these variously described abnormalities contribute to elevations in blood pressure.

We recently defined renin-linked heterogeneous deviations of calcium metabolism among subjects with essential hypertension, suggesting a state of calcium surfeit in some individuals, and of calcium deficit in others. Thus, the seemingly paradoxical and contradictory observations previously described may each be relevant in differing renin subgroups of hypertension. Specifically, serum Ca^{++} is directly related to plasma renin activity; low renin subjects have lower average Ca^{++} than either high renin hypertensive or normotensive control subjects. Serum magnesium is inversely related to plasma renin activity; low renin subjects have higher levels than other hypertensive or normotensive subjects (Fig. 4).[11]

The significance of these serum ionic alterations is further emphasized when calcium-regulating hormones are similarly analyzed. Serum levels of calcitonin, 1,25 dihydroxyvitamin D (1,25D) and parathyroid

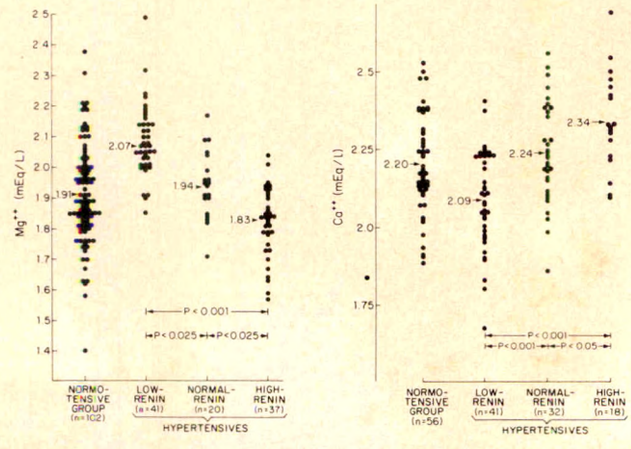

FIGURE 4. Serum levels of magnesium, **left,** and ionized calcium, **right,** in normotensive and low, medium and high renin subgroups of hypertensive subjects. Reproduced with permission from N Engl J Med.[11]

TABLE II Metabolic and Hormonal Comparison of Salt-Sensitive Versus Salt-Insensitive Subjects with Longer-Term Salt Loading

Group	ΔDBP (%)	PRA (ng/ml/hour)	ΔCa_{io} (mEq/liter)	ΔCT (%)	Δ1,25D (%)
Salt-sensitive (n = 8)	9.4 ± 0.9	1.5 ± 0.5	−0.08 ± 0.04	−26 ± 6	68.5 ± 9.0
Salt-insensitive (n = 5)	0.25 ± 1.3	3.0 ± 0.6*	+0.14 ± 0.05†	+1.6 ± 6	18.0 ± 17.7

* $p < 0.02$.
† $p < 0.01$ versus salt-sensitive.
DBP = diastolic blood pressure; PRA = plasma renin activity; Ca_{io} = serum ionized calcium; CT = calcitonin; 1,25D = 1,25 dihydroxyvitamin D.

hormone also vary among renin subgroups of essential hypertension (Table I). Calcitonin levels were lower in low renin subjects and higher in high renin subjects, as compared with either other hypertensive or normotensive control subjects, while levels of 1,25D were highest in low renin subjects compared with high renin hypertensive or normotensive control subjects. Parathyroid hormone levels were also highest in low renin hypertensive subjects.[12] These hormonal deviations were appropriate for the changes in serum Ca^{++} and highlight the biologic rather than just the statistical significance of the initially observed serum ionic deviations. Further, they suggest a broad-based link between the control of calcium metabolism and renin system activity in essential hypertension, and emphasize the pathophysiologic basis of renin profiling. Indeed, as we have suggested, plasma renin activity may reflect as well as modulate the steady-state distribution of calcium and magnesium across cell membranes.[11]

Clinical Heterogeneity of Hypertension—Salt Sensitivity, Calcium and Magnesium Supplementation

The question that naturally arises at this stage is what, if anything, might these linked ionic and hormonal deviations have to do with hypertension? Our preliminary observations suggest that blood pressure responses to varied dietary sodium intakes, as well as the ability of calcium and magnesium supplementation to affect blood pressure, differ among different renin subgroups of essential hypertension and can be predicted by either renin-sodium profiling or assessment of calcium metabolism.

Sodium sensitivity: Essential hypertensive outpatients, randomly allocated for 3 to 4 weeks each to low (<50 mEq/day) and high (>200 mEq/day) dietary sodium intakes, had blood pressure measurements, renin-sodium profiling and calcium metabolic variables analyzed. When categorized as sodium sensitive versus insensitive (Δ diastolic pressures >5% on high versus low sodium), sodium-sensitive subjects had significantly lower plasma renin activity, significant suppression of serum Ca^{++} and a greater elevation of 1,25D compared with sodium-insensitive subjects (Table II). Indeed, regardless of the definition of sodium sensitivity, continuous relations were observed between the change in pressure on high versus low dietary sodium and the changes in either serum Ca^{++} ($r = -0.90$, $p < 0.001$) or 1,25D ($r = 0.74$, $p < 0.01$).[13,14] Identical results were obtained when subjects were studied as inpatients on metabolic balance diets of low (10 mEq/day) and high (200 mEq/day) sodium content for 5 to 7 days each (Figs. 5 and 6).[15] Thus, it seems that blood pressure elevations with increased

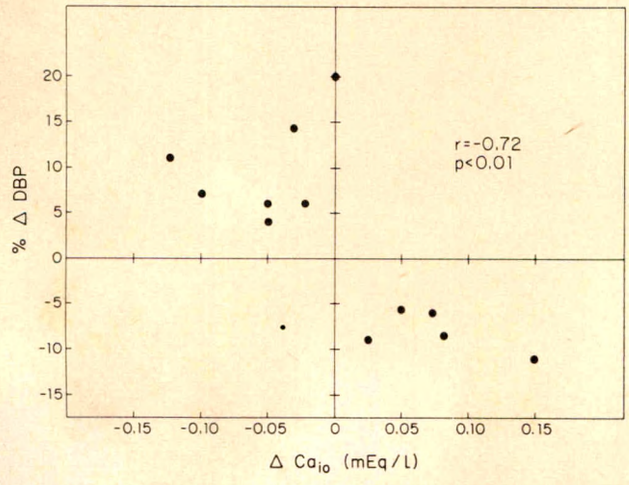

FIGURE 5. Effect of high versus low dietary salt intake on diastolic blood pressure as it relates to salt-induced changes in serum ionized calcium concentrations. %ΔDBP = percent change in diastolic blood pressure; ΔCa_{io} = change in serum ionized calcium.[15]

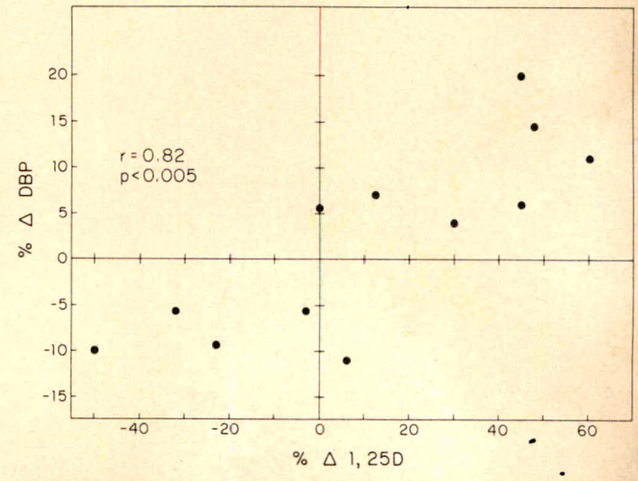

FIGURE 6. Effect of high versus low dietary salt intake on diastolic blood pressure as it relates to salt-induced changes in serum 1,25 dihydroxyvitamin D levels. %ΔDBP = percent change in diastolic blood pressure; %Δ1,25D = percent change in 1,25 dihydroxyvitamin D (data from references 14 and 15).

dietary sodium intake are characteristic of the low renin subject, that a unique calcium ionic and hormonal profile defines the sodium-sensitive state and that alterations in calcium metabolism may mediate the phenomenon. Regardless of pathophysiology, however, renin-sodium profiling and analysis of calcium metabolic indexes seem useful in identifying the sodium-sensitive subject. This has also been suggested by investigations of a putative natriuretic hormone in volume-related hypertension.[16]

The hypotensive efficacy of calcium and magnesium supplementation: Not only can renin activity and calcium indexes predict the spectrum of blood pressure responses to different dietary sodium intakes, but a similar analysis describes the effects of calcium and magnesium loading as well. We[17] and McCarron and Morris[18] reported preliminary results in treating essential hypertension subjects with oral calcium supplementation. In each study, blood pressure declined in some, rose in others and did not significantly change in many.[17,18] When these results were further analyzed by comparing the blood pressure response of an individual person with the pretreatment plasma renin activity or serum Ca^{++}, significant relations were observed. Calcium administered orally as the carbonate salt, 2 g/day for 5 days, to subjects on metabolic balance diets, preferentially lowered pressure in subjects with lower initial levels of renin activity ($r = 0.89$, $p < 0.005$) or lower initial levels of serum Ca^{++} ($r = 0.82$, $p < 0.005$).[19] Higher serum Ca^{++} levels or plasma renin activity were associated with either no clinical response or even a pressor response. Thus, we may be able to target specific hypertensive subgroups for whom calcium supplementation would be of benefit.

The exact opposite pattern of blood pressure response was observed with magnesium loading. Subjects on metabolic balance diets were given 2 g/day $MgSO_4$ intramuscularly for 3 to 5 days. Blood pressure was selectively lowered in normal and high renin subjects, while low renin subjects actually experienced a net pressor response (Fig. 7). Altogether, there was a significant inverse relation between the percent change in diastolic pressure and the initial plasma renin activity ($r = -0.77$, $p < 0.005$).[20]

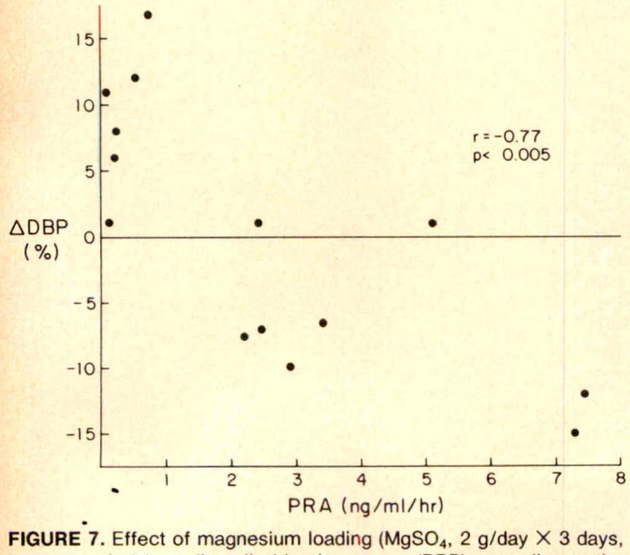

FIGURE 7. Effect of magnesium loading ($MgSO_4$, 2 g/day × 3 days, intramuscularly) on diastolic blood pressure (DBP) according to the initial plasma renin activity (PRA) in essential hypertensive subjects (data from reference 20).

Clinical Heterogeneity of Hypertension—Drug Therapy

While restriction of dietary sodium intake and, perhaps in the near future, calcium or magnesium supplementation may be initial maneuvers to benefit selected renin- or Ca^{++}-targeted subgroups of patients with mild to moderate hypertension, drug therapy still occupies a central position in the therapy of hypertension. Thus, it is of practical importance as well as of physiologic interest to ascertain whether measurement of plasma renin activity, serum Ca^{++} or other calcium metabolic indexes can similarly target subgroups of hypertensive patients who might preferentially benefit from specific drug classes. Indeed, historically, it has been the success of renin-sodium profiling in determining the blood pressure sensitivity to a variety of antihypertensive drugs that spurred continued research of renin system physiology and the utility of the vasoconstriction-volume analysis of hypertension.

Drugs and high-renin hypertension—beta blockers and converting enzyme inhibitors: Although the hypotensive effects of β-blocking drugs have long been established, the mechanism by which they exert their antihypertensive effects remains incompletely understood. Different observers have sug-

gested primary cardiovascular actions, central nervous system effects and inhibition of renin secretion as alternative hypotheses, and evidence exists for each hypothesis.[21] However, cardiac indices are themselves incapable of predicting the blood pressure response to β blockers, and subjects in whom pressure is lowered, unchanged or even elevated by these drugs may experience equivalent effects on, for example, cardiac output.[22] Similarly, at doses that have widely different capacities to penetrate the central nervous system, these agents show an equivalent ability to lower blood pressure.[23] On the other hand, evaluation of renin system activity does indicate that those patients most sensitive to β blockade are those with high ambient plasma renin activity, and that those with a low renin profile are insensitive to such therapy (Fig. 8).[24] With the recent development of drug therapy specifically designed to inhibit the renin-angiotensin system, such as converting enzyme inhibitors, the role of renin-mediated vasoconstriction in essential hypertension has been conclusively established. As with the blood pressure effects of β blockers, the hypotensive efficacy of an agent such as captopril is directly related to the initial plasma renin activity (Fig. 9).[25]

Thus, the physician who measures plasma renin activity in a given subject and finds it inappropriately elevated might consider initiating drug therapy with either β-blocking drugs or converting enzyme inhibitors. Further, the therapeutic implications of a high-renin profile apply even in the elderly, despite the decreased occurrence of high plasma renin activity in this population. Among elderly hypertensives, β blockers were shown to be preferentially effective in high renin subjects, while diuretics were more beneficial in lower renin subjects.[26,27]

Drugs and low renin hypertension—diuretics and calcium-channel blockers: According to the vasoconstriction-volume analysis of hypertension, those hypertensive subjects in whom plasma renin activity is suppressed would be predicted to be more volume sensitive and thus more sensitive to diuretic agents. Evidence that supports this has been reported by us and others (Table III). Thus, in choosing drug therapy, diuretics might be most reasonably considered in low renin hypertensive subjects.

In addition to diuretics, calcium-channel blocking agents have also emerged as selectively beneficial in low renin subjects; this has been shown thus far for both verapamil and nifedipine.[28] This selective benefit of calcium-channel blockade in low renin, volume-de-

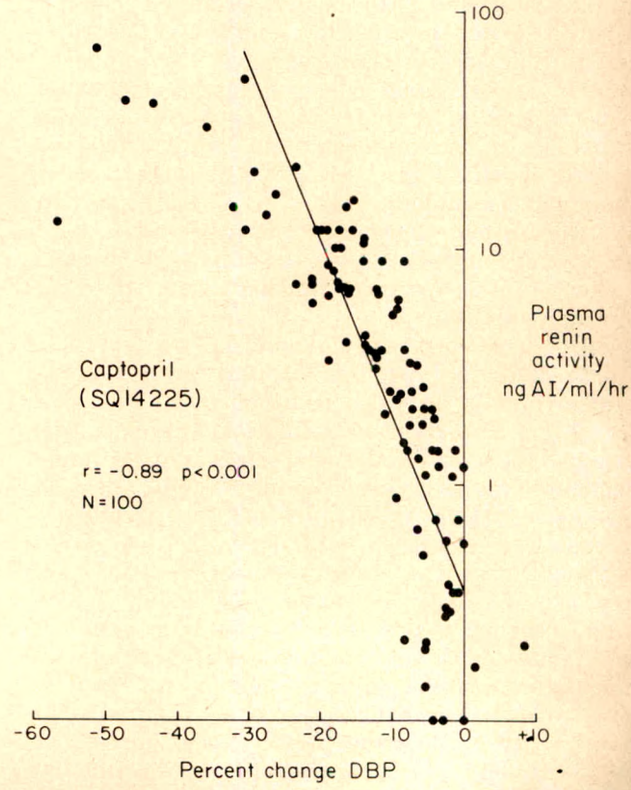

FIGURE 9. Hypotensive effects of converting enzyme blockade with captopril in relation to the initial plasma renin activity (cited in reference 25). DBP = diastolic blood pressure.

pendent hypertensive states has also been established in a variety of animal models and may indicate a greater dependence of hypertension on extracellular calcium in this form of hypertensive disease.[29,30] It may also reflect the lower serum Ca^{++} and higher magnesium levels characteristic of low renin hypertension. This ionic profile itself enhances the efficacy of calcium-channel blockade, as opposed to higher renin forms of hypertension, in which the observed higher serum Ca^{++} and lower magnesium levels would be expected to blunt calcium-channel antagonism.[31]

The Renin System, Calcium Metabolism and Rational Choice of Antihypertensive Therapy

On the basis of this discussion, it appears that renin-sodium profiling can provide a practical basis for therapeutic choices in hypertension. Moreover, recent knowledge linking calcium metabolism and renin system activity lends further significance to these choices. A consistent pattern is emerging, in which the initial deviations in serum Ca^{++} and magnesium observed among the different renin subgroups of hypertensives are such that maneuvers that exacerbate these deviations also exacerbate the hypertension. Similarly, successful dietary or drug therapy tends to reverse these ionic deviations and to reverse the hypertension.

Thus, high dietary salt intake exacerbates blood pressure in exactly those patients in whom serum Ca^{++} is most suppressed—those with a lower renin, lower Ca^{++} profile. Conversely, restriction of sodium intake, associated with higher serum Ca^{++} levels, benefits the salt-sensitive, low renin, lower Ca^{++} individual. Similarly, calcium supplementation is most beneficial in the same low renin, lower calcium subjects. Interestingly, these subjects also have higher initial levels of serum magnesium (as previously discussed), which calcium therapy lowers.[20] On the other hand, magnesium lowers serum Ca^{++} levels, can actually worsen hypertension in the lower renin, lower Ca^{++} person and is most beneficial in the high-renin, higher serum Ca^{++} subject, who has lower initial levels of magnesium.[20]

This parallel between the ionic and blood pressure effects of dietary sodium, calcium and magnesium supplements is now also being observed with drug therapy of hypertension. Diuretics have long been known to be capable of raising serum calcium values, while lowering levels of serum magnesium. The calcium-channel blocker, nifedipine, selectively beneficial in exactly the same type of hypertensive—the low renin, lower calcium subject—also raises Ca^{++} and lowers magnesium.[32] Thus, it is possible that diet and drug therapy may possess a common basis of action-reversing ionic deviations of circulating calcium and magnesium, as reflected by the ambient plasma renin activity. How these deviations are linked to renin system activity and how they relate to the abnormal intracellular levels of both cytosolic free calcium and free magnesium recently described[33,34] are currently unknown and afford exciting challenges for future research.

The Evolution of Antihypertensive Therapy

H. MITCHELL PERRY, Jr., MD

Beginning in the early 1950s, when a ganglioplegic agent and a vasodilator were used in combination to provide long-term control of severe hypertension, which neither drug alone could control, much has been learned about the management of hypertension from the use of new antihypertensive agents in man and from clinical trials of antihypertensive regimens. Some of this information includes: (1) the unexpected yet very real hazards as well as benefits associated with the long-term use of powerful drugs, in particular the original description of hydralazine-induced lupus, its relation to genetic markers and its association with control of hypertension; (2) the apparently decreasing need for antihypertensive drugs in subjects with well-controlled severe and moderate hypertension; (3) the identification of risk factors for the complications of hypertension and the quantitation of their effects; (4) the decrease in the incidence of hypertensive complications associated with the pharmacologic treatment of severe, moderate and, at least, the upper ranges of mild hypertension; (5) the possibility of designing a chemical to block a specific reaction and the realization that it would have broader than expected effects; and (6) the primary prevention of myocardial infarction in very high risk subjects.

(Am J Cardiol 1985;56:75H–80H)

The first real success in treating essential hypertension occurred about 50 years ago with the advent of surgical sympathectomy. Early treatment was uncertain, hazardous and unpleasant in the extreme; however, it held out hope for the future because it demonstrated that control was possible. In contrast, today virtually all essential hypertension can be controlled with relatively little difficulty. Although we still do not know the underlying mechanisms involved in maintaining an elevated blood pressure, many of the advances in the management of hypertension have provided important information. It seems timely to review what has been learned from the use of antihypertensive agents in man and from clinical trials of antihypertensive treatment. The marked decrease in the severity of hypertension in the United States (particularly in whites) during the last 30 years has dramatically shifted the emphasis from the treatment of malignant hypertension to the treatment of mild hypertension.

I would like to set the stage for my discussion by quoting some comments about the early treatment of hypertension made by E. Weiss in 1939:

> What has been done in an effort to reduce the blood pressure? Because of all ill-founded idea that protein was responsible for hypertension and kidney disease, the patient was denied meat and eggs, and especially red meat, which for some reason was looked upon with particular dread. His diet was rendered even more unpalatable by the withdrawal of salt. Sympathy would doubtless have been extended to this half-starved fellow except that he probably was not able to eat anyway, his teeth having been extracted on the theory that focal infection had something to do with hypertension. Even before this he had sacrificed his tonsils and had had his sinuses punctured because of the same theory. In case some food had been consumed, the slight colonic residue was promptly washed out by numerous colonic irrigations, especially during the period when the theory of auto-intoxication was enjoying a wave of popularity. To add to his unhappiness he was often told to stop work and exercise. Of course, he was denied alcohol and tobacco as well as coffee and tea, and as a climax to the difficulties of this unfortunate person, he may now fall in the clutches of the neurosurgeon, who is prepared to separate him from his sympathetic nervous system.[1]

This quotation reflects the desperate measures taken by physicians to treat a rapidly fatal disease for which no effective treatment had yet been developed.

Even before the introduction of effective drug therapy, some drugs were known to lower blood pressure acutely but transiently. Papaverine was the first such drug used to treat hypertension, followed by sodium nitroprusside and nitroglycerin.[2] Sodium nitroprus-

TABLE I Advances in Managing Hypertension and Major Findings

Year	Drug	Study	Significant Observation
1951	C_6 + hydralazine		Control of severe hypertension with 2 differently acting agents
1953	Hydralazine		Remissions associated with "toxic" autoimmune response
1955	Hydralazine		Hypertension controlled by "metal binders" and induced by cadmium and lead
1955	Chlorothiazide		Diuretics potentiate other antihypertensive agents
1956	C_6 + hydralazine		Remissions and partial remissions accompanying good control
1959		Framingham	Natural history of untreated hypertension and risk factor concept
1967 and 1970		VA study III	Benefit from treating severe and moderate hypertension
1972		VA study III	Same benefit for treating diastolic pressures in 70, 80 and 90-mm Hg range
1975	Captopril		Efficacy of designed converting enzyme inhibitor
1977		VA–NIH trial	Thiazide-induced increase in cholesterol
1979		HDFP	Possible benefit from treating mild hypertension to the mid80-mm Hg range
1979	Calcium antagonists		Cellular mechanism of vasodilatation
1980		ANBPS	Benefit from treating diastolic pressures of 95 to 110 mm Hg
1981		BMIS and BHAT	(Primary prevention of myocardial infarction)
1983		MRFIT	Possible drug-specific differences in benefit from treatment
1984		LRC trial	(Decrease in myocardial infarction by lowering cholesterol levels above 265 mg%)
1984		SHEP I	Control of isolated systolic hypertension by diuretics

Important observations were initially made as the result of new antihypertensive drugs and then as a result of multicenter trials. The dates approximate the time when the observations were made or published. The parentheses indicate studies that dealt with atherosclerosis; they are included because myocardial infarction is a major complication of hypertension. See text.

side was recognized by Johnson in 1929 as a very effective vasodilator.[3] Although it was tested as an antihypertensive agent, it was impractical therapeutically at that time because of its short duration of action, its unstable shelf life and the requirement that it be administered parenterally. In the 1930s and 1940s, before oral drugs capable of providing long-term control became available, surgical sympathectomy[4] and, subsequently, a very rigid low-sodium, high-potassium diet[5] controlled hypertension to some extent, indicating that the sympathetic nervous system and electrolytes were involved in the maintenance of an elevated blood pressure. Some of the important lessons subsequently learned from the use of new antihypertensive agents in man and from clinical trials of antihypertensive treatment are listed in Table I.

Long-Term Control of Severe Hypertension with Two Differently Acting Drugs

Modern pharmacologic therapy of hypertension had its beginning in the late 1940s, when routine screening for an antihypertensive effect identified the antituberculous hydrazine as a vasodilator and when 5- and 6-carbon methonium compounds were recognized as effective ganglioplegic agents.[6] Neither hydralazine nor the methonium compounds alone could do more than provide transient control of blood pressure. However, in 1951 Schroeder demonstrated that they could provide long-term control when administered together.[7] For the first time, patients with malignant hypertension had their blood pressure controlled and their rapidly progressive disease process abruptly halted. One of the patients in this initial group of 4 survived more than 10 years and another more than 20 years. Because the median survival time for untreated "malignant hypertension" was less than half a year,[8] it did not take long to demonstrate that therapy prolonged life. There were major problems in controlling blood pressure with these primitive drugs and in patient acceptance, but it had been clearly demonstrated that *attacking 2 different aspects of hypertension with 2 different drugs worked when neither one alone could provide long-term control.* These early antihypertensive agents were powerful but dangerous. Several years were needed to learn to use them effectively, during which time major and unexpected adverse effects appeared.

Good Hypertension Control and Both "Partial" and Complete Remission

Hypertensive patients with well-controlled blood pressure show a decreasing need for antihypertensive drugs, an effect currently being examined by various "step-down" studies. In the extreme case, this process leads to persistent normotension without drugs. The phenomenon was first reported in 1956;[9] it was not limited to a few unusual patients, but was a general characteristic of the entire hypertensive population in which diastolic pressure was adequately controlled by treatment. The report considered 114 moderately and severely hypertensive patients, all of whom took blood pressure readings at home. One month after hospital discharge, 79 were controlled (mean diastolic pressure at home <100 mm Hg) and 35 were uncontrolled. A year later, the mean diastolic pressure of the controlled patients had decreased slightly, and their intakes of hexamethonium and hydralazine had decreased to 74% and 89%, respectively, of their intake at 1 month after discharge. The mean diastolic pressure of the uncontrolled patients had increased slightly, and they were ingesting 97% and 98%, respectively, of their initial doses of the 2 drugs. After 3 years of treatment, the controlled group was slightly better controlled and needed an average of only 50% of their 1-month doses, while the uncontrolled group was no better controlled and was taking almost 80% of their 1-month doses. As those who have used these drugs know, the dosage range required for control is narrow, so this decrease in dosage for controlled patients was significant. *Thus, good control of blood pressure can lead to a lessening of the requirement for antihypertensive drugs.*

In a few patients, the phenomenon of diminishing drug requirements continued until complete discon-

tinuation of antihypertensive drugs was possible. In the 1956 report, "complete remissions"—normotension with no antihypertensive medicine—were reported in 10 of 114 patients.[9] Their pretreatment diastolic pressure ranged from 113 to 146 mm Hg. In 1966, 8 of these remissions were reported to have persisted for more than 10 years, although 3 patients noted the occasional use of diuretic or reserpine under "stress."[10] *Thus, long-term remissions were seen in 8 of 79 well-controlled patients.*

Hydralazine

The mechanism of action of this drug has never been clearly delineated beyond that it is a peripheral vasodilator that acts directly on vascular smooth muscle. Chemically, hydralazine is very reactive. In addition, it is a strong binding agent for certain metals. Metal binding is a property shared with other early vasodilators: nitroprusside, azide, thiocyanate and some experimental vasopressor mercaptans and pyrophosphates.

Hydralazine's ability to bind certain metals may or may not be important, but I mention it for 3 reasons: (1) because the patients treated with large doses of hydralazine were the ones who had remissions, and their clinical courses raised the possibility of depletion of an essential nutrient; (2) because of the possible competition between calcium and some of the metals bound by hydralazine and calcium; and (3) because of the recent report of a strong positive correlation between blood lead and blood pressure levels in the National Health and Nutrition Examination Survey sample of the U.S. population—in which a negative correlation with zinc raised the possibility of cadmium involvement.[11]

Because of the chelating properties of vasodilators, the effect of EDTA was tested in hypertensive animals. A dramatic antihypertensive effect was observed.[12] This led to the recognition that 2 ubiquitous nonessential trace metals, cadmium and lead, could induce something resembling human essential hypertension in rats. The doses required to induce hypertension were small and comparable to human *environmental* exposures.[13] Large body burdens of these 2 divalent metals in man might be expected to compete with calcium. Thus, cadmium and lead are possible contributors to human hypertension. The recently observed correlations from the National Health and Nutrition Examination Survey suggest further investigation.

Toxicity

The first 4 clinically effective antihypertensive agents produced major and unexpected toxic manifestations, emphasizing that long-term exposure to a drug with important effects on vital biologic functions is liable to produce unwanted effects as well. Hydralazine toxicity was the first to be recognized. This drug induced an autoimmune lupus-like syndrome in as much as 10% of the exposed population. The incidence was related to the extent of exposure in the susceptible portion of the population. Confined to genetically controlled "slow acetylators"[14] and almost exclusively to whites, this syndrome was of particular interest because its only recognized prodrome was normotension, which almost always persisted during the toxic phase and usually until symptoms had remitted.[15] For some toxic patients, this normotension developed into complete asymptomatic remission that persisted into the posttoxic period when patients were entirely asymptomatic and apparently well.[14] The remissions associated with autoimmune toxicity to hydralazine were different from, and not to be confused with, the previously described remissions associated with good control of pressure and the associated gradual decrease in medications. Under certain conditions (prolonged low hydralazine exposure after symptoms appeared), the remission rate in toxic patients approximated 50%.[16]

Hexamethonium, a ganglioplegic agent, was initially assumed to have no effect other than inhibition of all autonomic function, making life miserable for the patient, but in the process lowering his or her blood pressure. Hexamethonium, however, induced a fatal fibrinous pneumonitis characterized by extreme tachypnea without other symptoms in patients with malignant hypertension that had progressed to minimal azotemia.[17] This catastrophic response is still unexplained, but it does not evoke great concern, because hexamethonium is no longer used.

The use of reserpine, the third type of effective antihypertensive drug to become available, showed that a prompt effect can be forced from a long-acting drug, but that the very large doses needed to do so brought major toxic effects as the drug accumulated. Before this was recognized, doses from 10 to 100 times larger than the largest oral doses recommended today (2.5 to 25 mg/day) were prescribed and caused major depression in many patients, requiring prolonged hospitalization in closed wards.[18,19] Remembering these early psychoses, some physicians still hesitate to use reserpine. In today's doses, however, the drug is an effective adrenergic blocking agent, and its uniquely long half-life can be very helpful for patients who have difficulty remembering to take their medication. Although reserpine is usually characterized as a relatively weak antihypertensive agent, in head-to-head comparisons with other adrenergic blocking agents, it has always proved as good as, or better than, the competition. Because it is long-acting and is usually given in excess (the usual daily dose is 0.25 mg, but 0.05 mg provides 80% of the antihypertensive effect), 1 or 2 doses a week can provide a continuous antihypertensive effect. No other currently available agent, except perhaps guanethidine, is comparably long-acting.

Chlorothiazide became available in the mid1950s. Alone, it is a weak antihypertensive agent that has little effect on severe hypertension. Chlorothiazide and related thiazides, do, however, markedly potentiate the antihypertensive effect of most other antihypertensive drugs and, in so doing, serve the very important function of decreasing adverse effects. Initially, thiazide was considered to be without significant toxicity, which may very well be true; however, there is a recent suspicion that under certain ill-defined condi-

TABLE II Summary of Results from Veterans Administration Study[24,26,36]

Total Patients (treated and placebo)	Severity of Hypertension	Placebo Patients: Events/100 Patient Years	Treated Patients: Events/100 Patient Years	Ratio of Hypertensive to Arteriosclerotic Events	Therapeutic Efficacy Ratio
73	Severe (>115 mm Hg)	23	1.6	2.1	14
110	Moderate (105–114 mm Hg)	11	1.3	1.2	8.5
84	Mild (90–104 mm Hg)	9.3	4.7	1.1	2.0*

* Events that are not appropriately classified as either hypertensive or arteriosclerotic have been excluded, thus modifying the number of events and the therapeutic efficacy ratios slightly. The more rigidly derived therapeutic efficacy ratio, including all events, is only 1.5 for mild hypertensive subjects.

The randomization process rendered the treated and untreated populations very similar in age, race and other characteristics. The last 4 columns indicate frequencies of events as functions of the severity of hypertension for patients on placebo or active drugs, the ratio of hypertensive to arteriosclerotic events and the ratio of the event rate for placebo patients divided by the event rate for patients on an active drug.

tions, its long-term use may dangerously deplete the body stores of potassium and thereby induce fatal arrhythmia in rare susceptible patients. At present the possibility that thiazides actually have this toxic capability is nothing more than a suspicion; there is no proof.

In addition to the possibility of rare but catastrophic toxicity, there is recent concern regarding wrong-way chemical changes associated with thiazides. In 1976, the Veterans Administration–National Institutes of Health Mild Hypertension Feasibility Trial was the first double-blind, placebo-controlled study to confirm the suspected thiazide-induced increase in total cholesterol level.[20,21] The observed effect was not large, and there is a real question about its clinical significance. The increase during thiazide treatment averaged 5% from a pretreatment level of 200 mg%; it was greater for those with a lower pretreatment level and therefore for younger patients. The effect seemed to persist with little change for at least 2 years. Unfortunately, the increase did not include high-density lipoprotein cholesterol. Since this observation was made the effects of other antihypertensive agents on cholesterol have been studied in smaller series of patients. The reports are inconsistent, but a variety of agents has been observed to induce similar slight increases in cholesterol.[22] Hydralazine, in contrast to most other antihypertensive agents, significantly and consistently lowers circulating cholesterol, and the effect is sometimes much larger than the thiazide effect.[23] In addition to increasing total cholesterol by about 10 mg%, thiazide has also been observed to increase blood glucose by an average of 4.7 mg% and uric acid by an average of 1.4 mg%, and to decrease potassium by an average of 0.56 mEq/liter.[24] *There is no evidence, however, that any of these chemical effects is associated with an adverse clinical effect.*

The Framingham Study and Risk Factors

In addition to what has been learned from antihypertensive agents, epidemiologic studies have added greatly to our understanding of the hypertensive process. The Framingham study[25] provides our most useful insight into the natural history of untreated cardiovascular disease. Almost 6,000 inhabitants of Framingham, Massachusetts, enrolled in this study and were evaluated initially and then reevaluated biannually for various cardiovascular risk factors. From this come our best data on the incidence of hypertensive and atherosclerotic complications, particularly myocardial infarction and stroke, as functions of what are now designated "risk factors". For a 50-year-old white man, the risk of myocardial infarction can vary by as much as 20-fold, depending on the presence or absence of 6 risk factors. *Thus, the Framingham study quantitated the effect of common risk factors.*

Veterans Administration Study of the Benefits of Antihypertensive Treatment

The next major advance came in 1970, with the report of a randomized, double-blind, placebo-controlled study showing that treatment lowered morbidity and mortality for patients with diastolic pressure ≥105 mm Hg.[26] This report dramatically changed our whole way of thinking about hypertension; before 1970, many physicians were not enthusiastic about treating hypertension, because there was no proof of benefit. After 1970, *effective treatment was considered mandatory for a patient with diastolic pressure ≥105 mm Hg.*

This Veterans Administration study makes a number of other points; Table II presents the data for some of them. First, not unexpectedly, the untreated severely hypertensive patients had twice as many hypertensive events as atherosclerotic events, whereas the untreated mild hypertensive patients had equal numbers of hypertensive and atherosclerotic events. Second, without treatment, the morbid-event rate for the veteran population involved ranged from 23/100 patient years for severe hypertension to 9.3 for mild hypertension. Third, with treatment, the comparable-event rates were 1.6 and 4.7 for severe and mild hypertension, respectively. (The event rate for treated patients was higher for the mild hypertensive than for the severe hypertensive patients.) Finally, the "therapeutic efficacy ratio" ranged from 14 for severe hypertensives to 2 for mild hyertensives. Even with the small number of patients, "14" is obviously statistically significant, and so is "8.5" for moderate hypertension; however, "2" is not even close to being a significant value.

Goal diastolic pressure: One other observation of great potential significance emerged from this study. It has been generally assumed that the lower the treated diastolic pressure, the greater the benefit of treatment. For the treated veterans in this study, however,

there was no relation between the degree of blood pressure control and the decrease in morbid events. Thus, partial control of diastolic pressure was just as good as maximal control. Approximately one-third of the actively treated patients had average treated diastolic pressures in the 70-mm Hg range, one-third in the 80-mm Hg range and one-third in the 90-mm Hg range. The annual morbid-event rate was 12% for the entire treated group and 12% for each of these 3 subgroups.[27] In contrast, the annual morbid-event rate was 27% for the entire group of placebo-treated patients. Because the pretreatment diastolic pressures were similar for the 3 subgroups of actively treated patients, treatment produced an average fall in diastolic pressure of 27 mm Hg for the best controlled one-third compared with only 7 mm Hg for the worst controlled one-third of patients. Yet these 2 very different falls in diastolic pressure were associated with the same morbid-event rate. *This small data set suggests that nearly maximal benefit is attained with partial control.* Alternatively, it is consistent with the "Multiple Risk Factor Intervention Trial (MRFIT) anomaly."[28]

Primary Prevention of Myocardial Infarction

Although by definition primary prevention of myocardial infarction is distinct from treatment of hypertension, the goal is obviously the same for both therapeutic maneuvers. The British Practolol Study, which was discontinued because of serious toxicity, suggested that there was benefit from β blockade and that it was unrelated to the antihypertensive effect, because it was limited to the normotensive cohort.[29] The Norwegian Beta-Blocker Myocardial Infarction Study was the first to demonstrate clear protection against a *second* myocardial infarct, i.e., protection in very high risk patients. The difference in mortality between treatment and placebo appeared promptly and seemed to persist through the second year; the reduction in mortality with 33 months of treatment was 45%.[30] Aside from a higher baseline rate of myocardial infarction and shorter persistence of the beneficial effect, the subsequent Beta-Blocker Heart Attack Trial in the U.S. and Canada produced a similar result.[31]

The Coronary Primary Prevention Trial of the Lipid Research Clinics demonstrated that for middle-aged men with cholesterol levels above 265 mg% (the highest 5% of those with type II hyperlipoproteinemia), the cholesterol-lowering drug cholestyramine decreased cardiovascular mortality;[32] however, the extent to which this result can be extrapolated to other groups, including those with lower cholesterol levels, remains uncertain. *Thus, at minimum, it is reasonable to emphasize β blockade in lowering the blood pressure of hypertensive patients who are at high risk for myocardial infarction and to use cholesterol-lowering measures for those with very high levels.*[32]

The Benefits of Treating Mild Hypertension

The Hypertension Detection and Follow-up Program (HDFP) was initiated shortly after the 1970 report of the Veterans Administration study; the goal was to determine whether intensive treatment of hypertension by special therapists with nearly unlimited funds and time could lower mortality more than "regular treatment," which at that time was generally not intensive.[33] *The HDFP was, therefore, not a double-blind study of treatment versus no treatment.* Nonetheless, its results have been accepted by some as demonstrating great benefit by lowering the diastolic pressure of mildly hypertensive patients to the low 80-mm Hg range. The unusual design of HDFP and some of its unexplained findings raise questions about this interpretation. A 25% decrease in mortality between a special case group with average diastolic pressure of 83.4 mm Hg and a regular care group with diastolic pressure of 87.8 mm Hg is much greater than has ever been suggested by any other data. It is also much greater than HDFP observed in patients with moderate and severe hypertension; in them, regular care was actually better for moderately and severely hypertensive white women and for severely hypertensive white men. In addition to this unexpected result, HDFP had more than twice the mortality of 4 other studies with which a World Health Organization Expert Committee compared it;[34] this unexplainedly high mortality rate might have altered the blood pressure effect.

The similarly designed MRFIT failed to confirm the HDFP benefit in mild hypertension and raised some questions of its own.[28] In particular, the failure to demonstrate benefit raised the question of deleterious effects from intensive treatment. A MRFIT cohort of mild hypertensive subjects with electrocardiographic abnormalities was responsible for an excess of sudden deaths; it was this observation that first suggested that diuretic-induced hypokalemia *might* set the stage for fatal arrhythmia and sudden death in subjects with preexisting cardiac damage.

In contrast to HDFP and MRFIT, the Australian National Blood Pressure Study was a randomized, double-blind, placebo-controlled trial that demonstrated benefit from controlling pretreatment diastolic pressures of 95 to 110 mm Hg; it did not accept subjects with diastolic pressures <95 mm Hg, and so does not contribute information on the benefit of treating such patients.[35] In sharp contrast to HFDP, the Australian study observed little or no benefit from lowering the diastolic pressure of those subjects it did treat to <95 mm Hg. *Thus, although HDFP seemed to suggest benefit from lowering the diastolic pressure into the low 80-mm Hg range, the general trend of MRFIT and the Australian study suggests that treatment is not demonstrably helpful for subjects with diastolic pressures <95 mm Hg.*

Designed Drugs

Captopril was designed to inhibit the converting enzyme that splits angiotensin I into angiotensin II.[36] Its use demonstrated the therapeutic efficacy of a specifically designed enzyme inhibitor; however, it too raised some questions. Its antihypertensive effect was much more widespread than anticipated. It has been unexpectedly effective in low renin states when angiotensin II is apparently not involved in the maintenance of hypertension. It has been suggested, as a

partial explanation, that inhibiting the converting enzyme protects the vasodepressor nonapeptide, bradykinin.

Systolic Hypertension in the Elderly

Although the Framingham study suggested that systolic pressure is as good as or better than diastolic pressure in predicting cardiovascular complications, treatment of isolated systolic hypertension, which is so common in the "elderly", has only recently been seriously considered. Isolated systolic hypertension appears in persons in their mid50s; by age 75 or 80, it involves one-fourth of the population. A recent feasibility trial, Systolic Hypertension in the Elderly Program (SHEP), addressed the practicality of a randomized, double-blind, placebo-controlled trial to determine whether treating isolated systolic hypertension would diminish morbidity and mortality and whether such treatment would influence the incidence of dementia and depression, a major problem in that age group. The feasibility trial determined that isolated systolic hypertension could be easily controlled, usually with thiazides alone, and that there were no significant problems associated with treatment.[37] Practicality having been demonstrated, a full-scale SHEP is just beginning. *Thus, although no recommendations can be made at the moment, it seems likely that blood pressure can be lowered in the elderly and that there is no obvious danger in treating isolated systolic hypertension in this group; moreover, a definite answer on the advantages of such treatment will be available in a few years.*

Calcium Antagonists

The most recent entrant into the field of antihypertensive agents—the calcium antagonists—holds great promise for the future. They attack the fundamental defect in hypertension—and, for the first time, we have some ideas as to how such agents might act. As to their eventual place in the antihypertensive armamentarium, we can only speculate at present, although theory suggests that it will be important.[38]

In summary, we have learned a lot and, in the process, have observed some major changes in a common underlying disease process and its treatment. We have watched malignant hypertension virtually disappear and mild hypertension replace it as the focus of our attention. We have watched the rates of myocardial infarction and stroke decrease. Now we must work at cure and, subsequently, on prevention. We have some evidence that both of these are possible, and some clues are beginning to emerge to suggest how we might approach the problem.

Age, Race, Blood Pressure and Renin: Predictors for Antihypertensive Treatment with Calcium Antagonists

WOLFGANG KIOWSKI, MD, FRITZ R. BÜHLER, MD, MICHAEL O. FADAYOMI, MD, PAUL ERNE, MD, FRANCO B. MÜLLER, MD, ULF L. HULTHÉN, MD, and PETER BOLLI, MD

Age, race, pretreatment blood pressure and plasma renin activity have been related to the antihypertensive response to calcium antagonists in studies that included 215 patients with mild to moderate essential hypertension. Adverse effects necessitated withdrawal from therapy in about 10% of the patients. All calcium antagonists lowered blood pressure significantly and comparably without weight gain or reflex tachycardia. In a multiple linear regression analysis of 138 white patients, age, pretreatment blood pressure and renin activity were of independent and significant predictive value for the antihypertensive response. Stratification of patients into 3 age groups disclosed a greater effect in patients older than 60 years compared with those between 40 and 60 years and those below 40 years, respectively ($p < 0.01$). In 16 middle-aged black patients, antihypertensive therapy with a calcium antagonist proved highly efficacious. Monotherapy with a calcium antagonist may become a first-line treatment for essential hypertension, particularly in older patients who have low renin activity and possibly in black patients as well.

(Am J Cardiol 1985;56:81H–85H)

For more than 20 years calcium antagonists have been known to lower high blood pressure,[1,2] but their usefulness for the treatment of clinical hypertension has been recognized only recently.[3,4] Their introduction into a treatment regimen for hypertension affords the advantage of the good safety record that these drugs have acquired in the treatment of ischemic and hypertrophic obstructive heart disease as well as supraventricular arrhythmias. Calcium antagonists lower blood pressure by reducing elevated systemic vascular resistance.[3,5] It has been postulated that these drugs might specifically influence a deranged calcium entry–dependent, cellular vasoconstrictor mechanism in hypertension.[6,7] Clinically, calcium antagonists are most effective in older patients who often have low plasma renin activity.[4] However, the number of patients studied so far may not allow a generalization of these findings, and the relative impact of these factors is not clear because they are interrelated. In the present analysis we reexamined the predictive value of age, pretreatment blood pressure and plasma renin activity for the antihypertensive response to calcium antagonist monotherapy in patients with essential hypertension. Because the incidence of low renin hypertension is known to be high in blacks,[8] we also investigated the antihypertensive efficacy of calcium antagonist therapy in black African patients. We then compared the antihypertensive potentials of various calcium antagonists.

Patients and Methods

Predictors of antihypertensive response: One hundred and fifty-three patients with essential hypertension (60 women and 93 men, ranging in age from 18 to 85 years, mean age 42.2) from the Basel Hypertension Clinic participated in this prospective, placebo-controlled study. Previously untreated patients (n = 40) received placebo tablets 2 times a day for 2 weeks. In patients who were already receiving therapy, treatment was discontinued and placebo tablets were given 2 times a day for 3 to 4 weeks. At the end of the placebo period, diastolic blood pressure (Korotkoff V) was >100 mm Hg after 10 minutes in the seated position in all patients.

Plasma renin activity was measured simultaneously using a radioimmunoassay.[9] Blood pressure was measured with a standard mercury sphygmomanometer. Mean pressure was calculated as diastolic pressure plus one-third of the pulse pressure. Heart rate was counted from the radial pulse.

TABLE I Baseline Characteristics and Changes During Antihypertensive Therapy with Calcium Entry Blockers

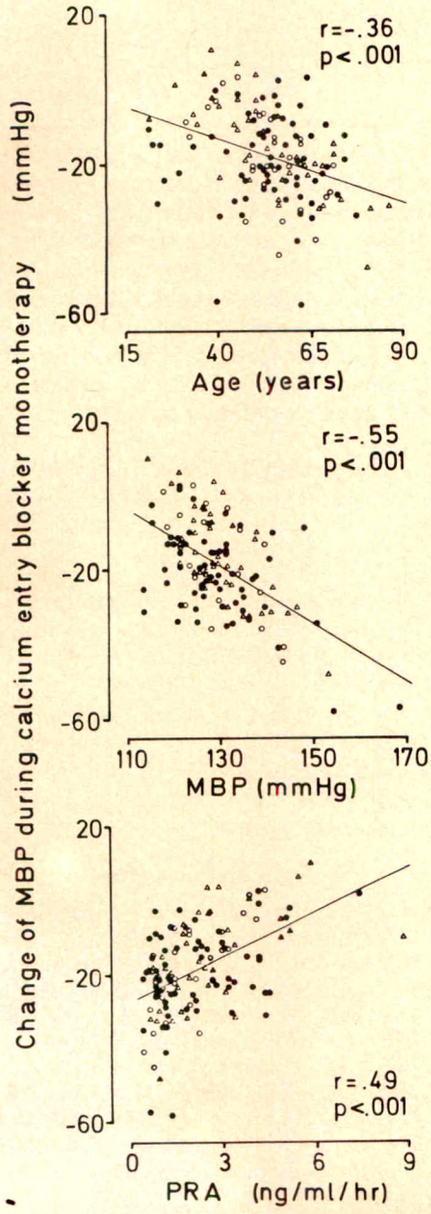

FIGURE 1. Linear relations between age, pretreatment plasma renin activity and blood pressure and antihypertensive response to calcium antagonists in essential hypertension. MBP = mean blood pressure; PRA = plasma renin activity; ● = nifedipine, n = 66; ○ = nitrendipine, n = 29; △ = verapamil, n = 43.

Antihypertensive effect, body weight and occurrence of adverse effects were assessed biweekly. If diastolic pressure remained >95 mm Hg, drug dosages were increased according to the therapeutic regimens that will be described.

Seventy-eight patients (50 men and 28 women, ranging in age from 21 to 76 years, mean age 42.6) received nifedipine in 20-mg tablets. Treatment was started with 20 mg, 2 times a day, and increased up to a maximum of 40 mg, 2 times a day. Treatment had to be discontinued within the first 4 weeks in 12 patients because of adverse effects. Therefore, 66 patients receiving an average dose of 52 mg/day for an average of 93 days were included in this analysis.

Thirty-one patients (20 men and 11 women, ranging in age from 29 to 70 years, mean age 53) received the dihydropyridine derivative nitrendipine; a starting dose of 20 mg, 2 times a day, was increased if needed to a maximum of 40 mg, 2 times a day. Two patients in this group had to be withdrawn in the first 4 weeks because of adverse effects. Thus, results from 29 patients who were treated with a mean dose of 35 mg/day for an average of 90 days were included in the statistical analysis.

Forty-four patients (23 men and 21 women, ranging in age from 20 to 85, mean age 53) were treated with verapamil given as a 120-mg, slow-release preparation.[4] Treatment was started with 120 mg, 2 times a day, and increased up to a maximum of 240 mg, 3 times a day. Treatment had to be discontinued after 2 weeks in 1 patient because of adverse effects. The remaining 43 patients were treated with an average dose of 427 mg/day for an average of 93 days.

Comparison of antihypertensive efficacy: The antihypertensive efficacy of various calcium antagonists was compared in 46 patients. Following a 2-week placebo period, patients were given 1 calcium antagonist for 3 months, followed by another 2-week placebo period. Next, a different calcium antagonist was prescribed for an additional 3 months. A comparison between verapamil (240 mg, 2 times day) and diltiazem (120 mg, 2 times a day) was made in 12 patients and between nitrendipine (20 mg, 2 times a day) and verapamil (240 mg, 2 times a day) in 15 patients. Tiapamil (600 mg, 2 times a day) and verapamil (240 mg, 2 times a day) were compared in 9 patients, and nitrendipine (20 mg, 2 times a day) and a new dihydropyridine derivative, PN 200-110 (Sandoz) (10 mg, 2 times a day), in 10 patients.

Race and antihypertensive efficacy: Sixteen black patients with essential hypertension from the Medifad Heart Center in Lagos, Nigeria (ranging in age from 37 to 59 years, mean age 48), were given placebo for 2 weeks followed by 20-mg nifedipine tablets 2 times a day for 6 weeks. Blood pressure was measured using a standard mercury sphygmomanometer with Korotkoff V taken as diastolic pressure. In these patients, blood pressure and heart rate were recorded in the supine position after 5 minutes of rest.

Statistical analysis: In order to analyze the impact of age, pretreatment blood pressure and plasma renin activity on the antihypertensive response to calcium antagonists in the first 153 patients, statistical evaluation was performed in the verapamil, nifedipine and nitrendipine groups separately and combined, using 1-way analysis of variance, paired and unpaired *t* tests, linear and multiple linear regression as well as χ^2 analysis. Intraindividual comparisons of the antihypertensive efficacy of the various calcium antagonists were performed by paired *t* test and linear regression analysis. Group statistics are shown as mean ± standard error of the mean as an index of dispersion.

Results

Age, renin and blood pressure as predictors of antihypertensive response: The 3 calcium antagonist treatment groups did not differ with respect to age and pretreatment characteristics (Table I). The effects of treatment in the 3 groups were comparable but heart rate decreased in verapamil-treated patients and remained unchanged in the others. Weight did not change in any group.

In an analysis of all patients, age and pretreatment blood pressure were directly related and plasma renin activity was inversely related to the antihypertensive effect of calcium antagonists (Fig. 1). Age and mean blood pressure were also inversely related to plasma renin activity ($r = -0.36$ and $r = -0.25$, $p < 0.01$ for both). A multiple linear regression analysis between age, pretreatment blood pressure and plasma renin activity as independent variables and the fall of mean blood pressure during long-term therapy showed a significant multiple linear correlation ($r = 0.49$, $p < 0.001$). All 3 variables had independent and significant effects on the antihypertensive response to calcium antagonists, with pretreatment blood pressure exhibiting the strongest influence ($F = 62.7$, $p < 0.01$) and plasma renin activity the weakest influence ($F = 18.2$, $p < 0.05$).

Although the linear correlation between age and response to calcium antagonists was rather weak (Fig. 1), older patients seemed to respond better to calcium entry blockers. When divided into 3 age groups, patients older than 60 years had, on the average, a greater blood pressure reduction compared with those between 40 and 60 years and those younger than 40 years ($p < 0.01$, analysis of variance). When considering a diastolic pressure <95 mm Hg during therapy as normal, 94% of patients older than 60 years normalized their blood pressure compared with 50% of middle-aged patients and 28% of younger patients ($p < 0.01$, χ^2).

Nifedipine caused adverse effects necessitating discontinuation of treatment in 12 patients within the first 4 weeks: 11 patients had flushing, severe headaches and migraine attacks and 1 patient had ankle edema. An additional 3 patients complained of headaches early during therapy and 7 patients noticed minor degrees of ankle edema. Verapamil monotherapy caused constipation in 5 patients, leading to withdrawal from therapy in 1. Nitrendipine was discontinued in 1 patient because of headache and ankle edema. Two other patients complained of hot legs, and 1 patient had a minor degree of ankle edema. There was no obvious relation between the occurrence of adverse effects and the patients' age or sex.

Intraindividual comparisons of different types of calcium antagonists: All calcium antagonists used in this study lowered blood pressure to a similar extent in the 4 crossover treatment groups. The comparability of their effects on blood pressure is further demonstrated by the close correlations observed between the reductions in blood pressure associated with the various drugs in these experiments (Fig. 2).

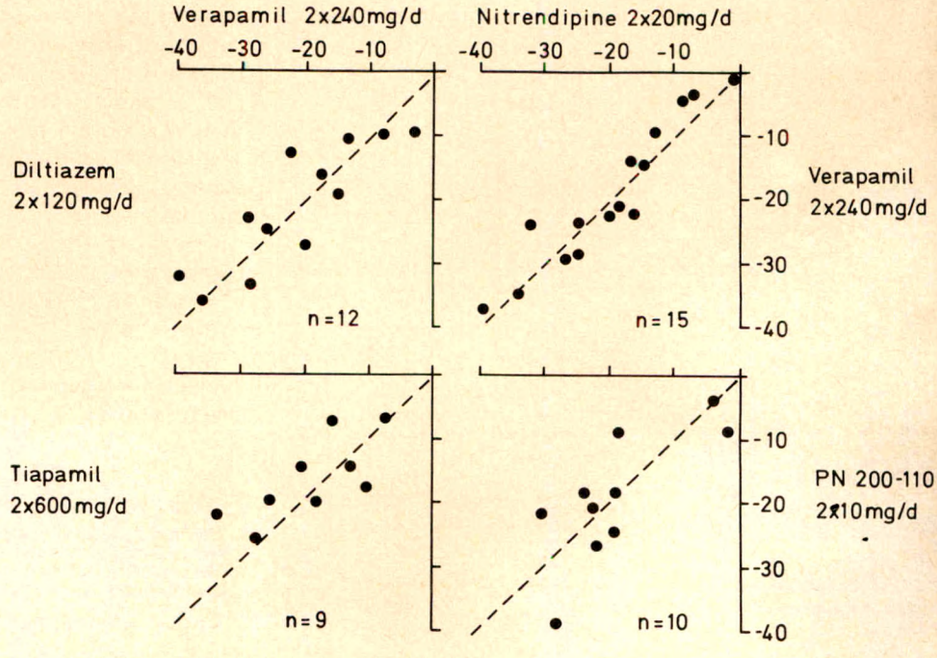

FIGURE 2. Blood pressure responses to various calcium antagonists in 4 groups of patients. Decreases of blood pressure observed with 1 compound were closely correlated with those observed after a crossover to a different drug.

Antihypertensive efficacy of nifedipine in black patients: Nifedipine was well tolerated in 16 black African patients. However, it was of interest that 5 patients reported polyuria as a minor adverse effect. As shown in Figure 3, blood pressure was reduced markedly and significantly (mean pressure 136.8 ± 2.2 vs 94.2 ± 1.39 mm Hg, $p < 0.001$) without significant changes in heart rate (75 ± 1.9 vs 79.9 ± 1.7) or weight (71.9 ± 3.1 vs 70.8 ± 3.1 kg).

Discussion

These analyses confirm the efficacy of different calcium antagonists in the monotherapy of patients with mild to moderate essential hypertension.[1–4] All drugs used in this study proved to be equally efficacious in both group and intraindividual comparisons. However, the dihydropyridine derivatives nifedipine and nitrendipine caused somewhat more adverse effects than did verapamil. Our experience with diltiazem is small but a low incidence of adverse effects has been reported for this drug.[10] Verapamil and diltiazem, however, should be used with caution in patients with sinus or atrioventricular nodal dysfunction or severely impaired cardiac contractility. Thus, better tolerated calcium antagonists without adverse effects on the heart are still needed. In dihydropyridine-treated patients, the antihypertensive effect was sustained over a mean observation period of 3 months without evidence of volume retention or reflex tachycardia, while the decrease in heart rate in verapamil-treated patients was probably due to the drug's negative chronotropic effects. The constellation of unchanged heart rate and absence of volume retention may explain why calcium antagonists remain effective during long-term monotherapy of hypertension. The mechanisms behind these findings are not apparent from our study

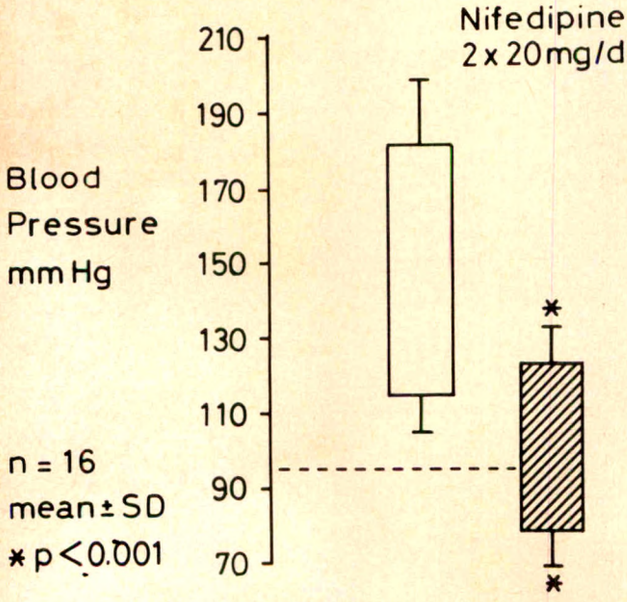

FIGURE 3. Response of blood pressure to nifedipine therapy in 16 black African essential hypertensive patients. SD = standard deviation.

but a diuretic effect,[11] interference with the renin-angiotensin-aldosterone system,[12] resetting of arterial baroreflexes[5] and interference with sympathetic mechanisms[13,14] must be considered.

Age, pretreatment blood pressure and plasma renin activity had significant and independent predictive effects with respect to the antihypertensive efficacy of calcium antagonists. However, none of the linear correlations at first seemed sufficiently close to be of help in guiding the clinical use of calcium antagonists in patients with hypertension. In particular, the correlation between pretreatment blood pressure and antihypertensive response is not unique to calcium antagonists; it applies to other antihypertensive drugs as well.[15]

Despite the weak linear relation between patient age and antihypertensive effect of calcium entry blockers, age nevertheless seems to be the most useful predictor of response to calcium antagonists. Thus, patients older than 60 almost uniformly showed a considerable decrease in blood pressure. Not only did older subjects show a greater average fall in blood pressure, but also a significantly greater proportion of them had normalized diastolic pressure compared with the other patients. We can only speculate about the reason for this good response. Reduced baroreflex sensitivity is known to occur with older age and hypertension.[16] Therefore, arterial vasodilatation and decrease in blood pressure might lead to less reflex stimulation, which could enhance the antihypertensive action of a calcium antagonist. Pharmacokinetic differences such as increased bioavailability in older patients could also play a role, but the potential importance of these factors remains to be defined.

It is also of interest in this context that patients with low renin activity and black patients seemed to respond particularly well to calcium antagonists. Black patients are known to have a high incidence of low renin hypertension[8] and this subset of patients is also characterized by poor counterregulatory mechanisms;[17] both of these findings could serve to explain our clinical observations. However, confirmatory experience is needed before calcium antagonists can be widely recommended in black patients.

It is also noteworthy that the incidence of adverse effects in older patients was similar to that in younger patients. Diuretics have often been used in older low renin patients[18] and in black patients,[19] but the widespread use of these drugs has been clouded by the suggestion of increased cardiovascular mortality, as well as other adverse effects, despite satisfactory blood pressure control.[20] Calcium antagonists might thus be an attractive alternative to diuretics for treatment of hypertension in older low renin patients and in black patients as well.

Effects of Diltiazem on Serum Lipids, Exercise Performance and Blood Pressure: Randomized, Double-Blind, Placebo-Controlled Evaluation for Systemic Hypertension

PETER E. POOL, MD, SHIRLEY C. SEAGREN, BA, and ANTONE F. SALEL, MD,
with the statistical assistance of M. LORIE SKALLAND, MS

Treatment of hypertension with diuretics, β blockers and α blockers may be associated with adverse effects on exercise performance, serum lipids and blood chemistries, as well as with orthostatic effects and fluid retention. A randomized, double-blind, placebo-controlled trial of a sustained-release preparation of diltiazem as sole therapy for moderate essential hypertension was conducted. Diltiazem was administered 2 times a day (360 mg/day) to 16 patients and placebo to 14 patients in a 12-week study. Average supine blood pressure with diltiazem therapy fell from 161/100 to 144/87 mm Hg without fluid retention or orthostatic effects. In an open-label study, patients from the placebo and diltiazem groups continued with diltiazem therapy. At an average of over 8 months, supine blood pressure on diltiazem was 147/88 mm Hg, and after withdrawal to single-blind placebo, average supine blood pressure increased to 173/104 mm Hg. All changes were significant compared with baseline and placebo ($p < 0.01$). On diltiazem therapy, maximal treadmill exercise was increased by an average of 55 seconds ($p < 0.01$), whereas heart rate, blood pressure and double product (heart rate × blood pressure) were reduced at submaximal exercise, and heart rate and double product were reduced at maximal exercise. No changes in serum glucose, potassium or uric acid were found. No adverse effects on serum lipids occurred. Diltiazem treatment was associated with an increase in high-density lipoprotein cholesterol (52 to 60 mg/dl, $p < 0.006$) and a decrease in total cholesterol:high-density lipoprotein cholesterol ratio (4.7 to 4.2, $p < 0.05$). Adverse reactions to diltiazem were not severe, and only modestly greater than adverse reactions to placebo. Thus, diltiazem is an acceptable monotherapy in moderate essential hypertension with certain significant advantages over diuretics and β blockers.

(Am J Cardiol 1985;56:86H–91H)

The antihypertensive effects of calcium-channel blockers have been well known for years,[1] but until recently, their therapeutic role has been considered secondary.[2] A growing realization of the potential adverse effects of the most common first-line agents—β blockers and diuretics[2]—and new knowledge of the role of calcium in hypertension[3] have led to the consideration of calcium-channel blockers as first-line therapy. As the stepped-care approach to hypertension is abandoned, the potential advantages of calcium-channel blockers over diuretics and β blockers should be considered.

This study investigated, in a prospective, randomized, double-blind, placebo-controlled parallel trial, the effects of diltiazem as sole therapy in the treatment of moderate essential hypertension. Special attention was given to diltiazem's efficacy, both short and long term, its orthostatic effects and tolerability, its effects on blood chemistries, especially serum lipids, and its effects on exercise performance.

Methods

The protocol was approved by this institution's Human Research Committee, and each patient consented in writing to participate in the study.

Design: All patients entering the study were required to have essential hypertension—defined as a stable resting supine diastolic pressure between 95 and 110 mm Hg. All patients were withdrawn from any prior antihypertensive medication for at least 2 weeks and were placed on single-

blind placebo. After 7 to 10 days on placebo, the patients began a series of weekly visits, during which resting supine pressures were obtained; the average of 3 measurements was recorded as the pressure at each visit. For a subject to qualify, his or her resting supine diastolic pressure on 2 consecutive weekly visits had to be between 95 and 110 mm Hg and could not vary by more than 7 mm Hg between visits. The average of these 2 visits was used as baseline. Patients requiring more than 4 weeks for stabilization were considered labile and they were excluded. Patients were also excluded if they had other significant disease, sick sinus syndrome or greater than first-degree atrioventricular block. No patient was allowed to take any concomitant medication known to affect blood pressure, including oral contraceptives and psychotropics.

After baseline was established, each patient underwent dose titration with 1 capsule 2 times a day for the first 2 weeks, then 2 capsules 2 times a day for the second 2 weeks and 3 capsules 2 times a day for the third 2 weeks, if required. For those patients randomized to diltiazem, this made the daily dose 120, 240 and 360 mg, respectively, of the sustained-release preparation. Dosing continued upward until a 10% or greater reduction in diastolic pressure was achieved or until the highest dosage was reached. After a further 4-week administration period, a final evaluation was made (week 12). Electrocardiograms, routine hematologic studies, chemistry analysis and urinalysis were performed prestudy, at end of titration and at week 12.

After week 12, patients on diltiazem were allowed to continue on open-label diltiazem for an additional 10-month period, while those on placebo were allowed to begin titration and maintenance of open-label diltiazem. At the end of 10 months, a single-blind placebo withdrawal period was used to evaluate continuing blood pressure control. Patients on placebo were observed at 2-week intervals until supine diastolic blood pressure was >95 mm Hg, and 1 week after this they had another follow-up visit.

Measurements of blood pressure and heart rate: Patients were evaluated in the morning, 10 to 14 hours after their last dose of medication. They were asked to refrain from smoking or using caffeine-containing beverages before their visit and had been fasting for at least 2 hours. Measurements were made using the same arm and usually by the same person. Systolic and diastolic blood pressure were determined by phase I and V of the Korotkov sounds. Supine pressures were recorded after 10 minutes of rest with the arm positioned at the patient's side. Standing pressures were measured with the arm horizontal at the level of the fourth intercostal space at the sternum. Both supine and 5-minute standing pressures were based on an average of 3 determinations taken at least 1 minute apart. Pulses were counted for 30 seconds after the final pressure determination of a set. Immediate standing pressure was a single determination.

Exercise testing: Patients underwent exercise testing according to the Bruce protocol[4] at the prestudy visit (a "training" test), at the end of the placebo run-in (baseline), at the end of the titration period and at the end of the study (week 12). Blood pressure, heart rate, double product and ST change (V_5 and aVF) were obtained during the last 30 seconds of each 3-minute stage, at end of exercise and twice during recovery. Maximal exercise measurements were determined at the end of exercise.

Submaximal measurements were made at the end of the stage before the last stage of exercise during which more than 60 seconds of exercise occurred. If the patient failed to exercise 60 seconds into stage 2, the end of stage 1 was used as submaximal exercise.

Measurement of serum lipids: Serum lipid fractions were assessed by quantitating total cholesterol,[5] high-density lipoprotein (HDL) cholesterol,[6] low-density lipoprotein cholesterol, very low-density lipoprotein cholesterol, the total cholesterol:HDL cholesterol ratio and total triglycerides[7] at the prestudy visit (baseline), at end of titration and at end of week 12. Additional assessments were made at the end of long-term observation. All samples were drawn after a 14-hour fast.

Subjects: Fifty patients met the initial entry criteria and were enrolled in the placebo run-in after randomization (Table I). Thirteen of these (8 placebo and 5 diltiazem) failed to qualify during run-in, 1 patient in the diltiazem group requested withdrawal during this stage and 2 (1 in each group) were dropped for adverse reactions to placebo. Four patients (2 in each group) completed the entire trial and were found in retrospect not to have met stability criteria. They are treated in a separate analysis. The remaining 30 patients (14 placebo and 16 diltiazem) were analyzed in the parallel portion of the blood pressure data. These patients, plus the 4 just mentioned who completed the entire trial, constitute the patients in the analyses on exercise and adverse reactions. The same group, less 1 placebo patient who was excluded because of familial hyperlipidemia, constitutes the patients in the short-term lipid analysis. After the 12-week trial, 14 placebo patients began to take diltiazem, and they, together with 12 of the original diltiazem patients, are those analyzed in the long-term blood pressure trial. The long-term lipid analysis included the 33 patients from the short-term trial (with some of those on placebo beginning to take diltiazem) minus 2 placebo patients, 1 of whom never took diltiazem and another of whom had no lipid determination on diltiazem.

Statistical analysis: Demographic characteristics at baseline were compared using a χ^2 test for sex, race and smoking characteristics and Student's t test for age, weight and duration of hypertension to validate the randomization process.[8] To determine whether the diltiazem group and the placebo group were comparable at baseline, Student's t tests were performed for each key parameter using only the baseline data. No significant differences were found for any parameter, with the exception that the randomization produced a significantly higher systolic and diastolic blood pressure in the placebo group both at submaximal and maximal exercise.

To determine whether diltiazem and placebo groups differed significantly at other times during the study, split-plot analyses of variance were performed on the differences from baseline. If the treatment by evaluation interaction was not statistically significant (i.e., the 2 treatments were similar for the response from end of titration to end of the study), an overall statement about the treatment (diltiazem versus placebo) could be made. For any parameters exhibiting treatment by evaluation interaction, Student's t tests were performed on the differences from baseline at each evaluation.

To determine whether significant changes from baseline occurred at any evaluation for either treatment, 2-way analyses of variance were performed by treatment for each parameter in each position using the actual data. If the overall F test for the evaluation effect was significant at the 0.05 level, Duncan's multiple comparison procedure was used to determine which evaluations differed significantly from baseline.

The significance of diltiazem's long-term effects on blood pressure and lipid levels was determined by the paired t test, comparing the last observation with the baseline determination for blood pressure and the prestudy value for lipids.

Categorical analysis was performed by determining whether patients achieved the goal blood pressure reduction of 10% of baseline supine diastolic pressure. At each evaluation, a 1-tailed Fisher's exact test was performed to compare the percentage of diltiazem and placebo patients reaching goal.[8]

TABLE I Summary of Patient Demographics

	Diltiazem (16)	Placebo (14)
Sex	10 M, 6 F	10 M, 4 F
Age (year ± SE)	60 ± 2	61 ± 3
Race	15 white, 1 other	14 white
Height (in ± SE): M	69 ± 1	68 ± 1
F	64 ± 1	63 ± 1
Weight (lb ± SE): M	182 ± 9	187 ± 7
F	157 ± 8	134 ± 6
Smoker	1 (+), 15 (−)	1(+), 13 (−)
Hypertension duration (years)	16 ± 2	14 ± 3

SE = standard error.

TABLE III Average Blood Pressure and Heart Rate (± SE) in the Long-Term Study—Average 34.4 Weeks (26 Patients)

	Baseline	Last Observation	p
Systolic (mm Hg)			
Supine	164 ± 4	147 ± 3	<0.0001
Standing (5 min)	165 ± 4	145 ± 3	<0.0001
Diastolic (mm Hg):			
Supine	100 ± 2	88 ± 2	<0.0001
Standing (5 min)	102 ± 2	88 ± 2	<0.0001
Heart Rate (beats/min):			
Supine	67 ± 2	66 ± 2	NS
Standing (5 min)	74 ± 2	70 ± 2	=0.032

NS = not significant; SE = standard error.

TABLE II Average Blood Pressure and Heart Rate (± SE) in the Controlled 12-Week Study in 30 Patients (16 Diltiazem [D], 14 Placebo [P])

	Baseline		End of Titration		End of Week 12	
	D	P	D	P	D	P
Systolic (mm Hg):						
Supine	165 ± 2	167 ± 6	145 ± 4†	169 ± 6	144 ± 5†	171 ± 7
Standing (5 min)	164 ± 5	168 ± 6	143 ± 4*	166 ± 6	149 ± 5*	171 ± 6
Diastolic (mm Hg):						
Supine	100 ± 1	100 ± 1	86 ± 2†	99 ± 1	87 ± 2†	101 ± 3

Heart rate (beats/min):						
Supine	64 ± 2	69 ± 3	62 ± 2	71 ± 3	62 ± 2	70 ± 3
Standing (5 min)	69 ± 3	77 ± 3	68 ± 2	76 ± 3	70 ± 2	75 ± 4

* p <0.01 diltiazem versus placebo.
† p <0.001 diltiazem versus placebo.
SE = standard error; all blood pressures on diltiazem are significantly different from baseline, p <0.01; no blood pressure on placebo is significantly different from baseline; no heart rate is significantly changed from baseline on diltiazem or placebo.

A final analysis was made to include the 4 patients who failed eligibility criteria but who received the drug through the double-blind portion of the protocol. The analysis yielded the same qualitative results.

Results

Demographics: The results of randomization of patients to diltiazem or placebo did not indicate any significant differences owing to sex, age, race, size, smoking history, concomitant diseases or duration of hypertension (Table I). Baseline blood pressure values (± 1 standard error) in the group randomized to placebo averaged 167 ± 6/100 ± 1 mm Hg supine, and 168 ± 6/102 ± 2 mm Hg after standing for 5 minutes. These values did not differ from values of subjects randomized to diltiazem, which averaged 165 ± 2/100 ± 1 mm Hg supine and 164 ± 5/103 ± 1 mm Hg standing.

Dosage: For each patient, dosage was titrated for best response. All patients reached a daily dosage of 360 mg of the sustained-release preparation of diltiazem, which was given 2 times a day.

Effects on blood pressure: Both systolic and diastolic blood pressure values were significantly reduced in patients treated with diltiazem compared with those receiving placebo. This was true for blood pressure taken in both the supine ($p < 0.001$) and the standing ($p < 0.01$) position at end of titration and at week 12 after 4 weeks of maintenance therapy at a constant dosage (Table II).

Average supine blood pressure at end of titration and at week 12 in the placebo group was 169/99 and 171/101 mm Hg, respectively. In those patients treated with diltiazem, average supine blood pressure was 145/86 at end of titration and 144/87 mm Hg at week 12. Average standing blood pressure at end of titration and at week 12 was, in the placebo group, 166/100 and 171/102 mm Hg, respectively, whereas in the group treated with diltiazem it was 143/89 and 149/88 mm Hg, respectively.

Supine diastolic pressure was reduced 10% or more in 11 of 16 patients treated with diltiazem compared with 1 of 14 patients treated with placebo ($p < 0.0007$) at end of titration. At week 12, 10 of 16 patients treated with diltiazem showed a 10% or more reduction of blood pressure, compared with 1 of 14 treated with placebo ($p = 0.002$).

Long-term effects of diltiazem on blood pressure were evaluated in 26 patients—those randomized to diltiazem who continued on treatment after the medium-term study and those who finished the medium-term study on placebo and were then placed on open-label diltiazem therapy. These subjects were followed for an average of 34.4 ± 11.4 (standard deviation) weeks (Table III). At their last observation, these patients had an average supine blood pressure of 147/88 mm Hg, compared with their baseline value of 164/100 mm Hg ($p < 0.0001$). In the standing position, the last observation blood pressure was 145/88 mm Hg, com-

TABLE IV Exercise Data in the Controlled 12-Week Study in Diltiazem (D)- and Placebo (P)-Treated Patients

		Submaximal Exercise		Maximal Exercise (end)		End of week 12 Versus Baseline	
		Baseline	End of Week 12	Baseline	End of Week 12	Submaximal	Maximal
Time (s)	D	—	—	602 ± 61	657 ± 58	—	<0.01
	P	—	—	674 ± 47	692 ± 44	—	NS

	P	104 ± 2	103 ± 3	88 ± 7	77 ± 9	NS	NS
HR (beats/min)	D	137 ± 5	120 ± 5	158 ± 5	145 ± 5	<0.01	<0.01
	P	143 ± 3	139 ± 4	164 ± 3	164 ± 4	NS	NS
DP × 100	D	266 ± 13	222 ± 15	317 ± 12	279 ± 11	<0.01	<0.01
	P	297 ± 10	304 ± 12	358 ± 11	358 ± 9	NS	NS
ST V_5 (mm)	D	−0.3 ± 0.2	−0.2 ± 0.1	−0.6 ± 0.3	−0.2 ± 0.2	NS	NS
	P	−0.5 ± 0.3	−0.4 ± 0.3	−0.8 ± 0.3	−0.5 ± 0.3	NS	NS
ST aVF (mm)	D	−0.5 ± 0.2	−0.2 ± 0.2	−0.7 ± 0.3	−0.2 ± 0.2	<0.05	<0.01
	P	−0.6 ± 0.4	−0.3 ± 0.4	−0.8 ± 0.4	−0.5 ± 0.5	NS	NS

SBP = systolic blood pressure; DBP = diastolic blood pressure; HR = heart rate; DP × 100 = double product (SBP × HR) × 100; ST V_5 = ST-segment position in V_5; ST aVF = ST-segment position in aVF; NS = not significant.

At maximal exercise, significant differences occurred between diltiazem and placebo in HR ($p = 0.0004$) and DP × 100 ($p = 0.0004$); at submaximal exercise, significant differences occurred between diltiazem and placebo in SBP ($p < 0.01$), DBP ($p < 0.03$), HR ($p < 0.0001$) and DP × 100 ($p < 0.0001$).

pared with a baseline value of 165/102 mm Hg ($p < 0.0001$).

To be certain that the amelioration in blood pressure observed long-term was not due to improvement in underlying disease, 12 patients were withdrawn to single-blind placebo after 10 months of open diltiazem administration. They were seen every 2 weeks until supine diastolic blood pressure was >95 mm Hg, and then observed again 1 week later. This blood pressure level was reached in 2 weeks by 7 patients, in 3 weeks by 1 (who was on vacation at 2 weeks), in 4 weeks by 2 and in 6 weeks by 1. Average baseline supine pressure in this group was 173/104 mm Hg; at last diltiazem observation, it was 144/84 mm Hg; at an average of 2.6 weeks after withdrawal, it was 172/100 mm Hg; and 1 week later, it was 170/100. Standing pressure values followed a similar pattern.

Effects on heart rate: No clinically significant changes in heart rate were produced by treatment with either placebo or diltiazem. A small, statistically significant ($p = 0.032$) decrease in heart rate was noted during the long-term study, in the standing position only, where the heart rate fell from an average of 74 to 70 beats/min (Tables II and III).

Orthostatic effects: Orthostatic effects on heart rate and blood pressure in patients treated with diltiazem were compared with those in patients treated with placebo at the end of 12 weeks. A small and essentially identical drop in systolic pressure was noted in each group, with no change in diastolic pressure. In the placebo group, supine pressure fell from 171/101 to 167/102 mm Hg immediately upon standing, whereas with diltiazem patients, the pressure fell from 144/87 to 142/87 mm Hg. The reflex increase in heart rate was similar in both groups.

Effects on exercise performance (Table IV): In the 12-week study, the maximum duration of exercise increased an average of 55 seconds in the diltiazem group ($p < 0.01$) and 18 seconds in the placebo group (difference not significant) compared with baseline.

TABLE V Average Serum Lipid Levels (± SE) in the Controlled 12-Week Study (33 Patients, 18 Diltiazem [D], 15 Placebo [P])

		Baseline	End of Week 12	p
Cholesterol (mg/dl)	P	222 ± 10	225 ± 9	NS
	D	231 ± 7	245 ± 8	NS
HDL (mg/dl)	P	52 ± 6	54 ± 4	NS
	D	49 ± 3	56 ± 4	<0.05
LDL (mg/dl)	P	145 ± 9	146 ± 8	NS
	D	159 ± 7	164 ± 6	NS
VLDL (mg/dl)	P	25 ± 3	24 ± 3	NS
	D	25 ± 3	25 ± 3	NS
Cholesterol/HDL	P	4.74 ± 0.39	4.43 ± 0.33	NS
	D	4.99 ± 0.28	4.62 ± 0.33	NS
Triglycerides	P	126 ± 16	118 ± 18	NS
	D	127 ± 15	120 ± 13	NS

HDL = high-density lipoprotein; LDL = low-density lipoprotein; VLDL = very low-density lipoprotein; NS = not significant; SE = standard error.

No significant differences between diltiazem and placebo were found.

However, the difference between the groups was not significant. Blood pressure, heart rate and double product (heart rate × blood pressure) were all significantly decreased by diltiazem at submaximal exercise, whereas only heart rate and double product were decreased at maximal exercise. The differences from baseline values at maximal exercise were smaller than those at submaximal exercise. These same parameters, which were significantly different from baseline, were also significantly different from placebo (see Table IV). There was significantly less ST-segment depression in lead aVF in the diltiazem group at end of week 12 compared with baseline, both at submaximal and maximal exercise, but this difference was not significant compared with placebo, and its clinical significance is uncertain.

Effects on serum lipids and blood chemistries: In the medium-term 12-week study (Table V), the only significant change in serum lipids was an increase in HDL cholesterol in the diltiazem group from 49 ± 3

TABLE VI Average Serum Lipids (± SE) in the Long-Term Study—Average 29.5 Weeks (31 Patients)

	Baseline	Last Observation	p
Chloesterol (mg/dl)	227 ± 6	233 ± 7	NS

Dyspepsia	2	0
Nocturia	2	1
Paresthesia	1	2
Headache	1	4
Nausea	0	2
Insomnia	0	2
Chest pain	0	2
Other	5	6
Total	23	22

All adverse effects that occurred more than once in either the diltiazem or placebo group are listed, regardless of severity. Those occurring only once are listed under "other."

to 56 ± 4 mg/dl ($p < 0.05$) between baseline and week 12. Other changes that exceeded 5% in magnitude but that were not statistically significant were an increase in cholesterol from 231 to 245 mg/dl in the diltiazem group and a fall in cholesterol:HDL ratio and triglycerides in both groups.

In the long-term study, which involved 31 patients for an average of 29.5 weeks, HDL cholesterol increased from 52 ± 3 to 60 ± 3 mg/dl ($p < 0.006$), and the cholesterol:HDL ratio decreased from 4.7 ± 0.2 to 4.2 ± 0.2 ($p < 0.05$). No other changes greater than 5% in magnitude occurred (Table VI). No clinically or statistically significant changes were found in any analysis of serum glucose, creatinine, potassium or uric acid.

Adverse reactions: Thirty-four patients completed the medium-term 12-week study. Nine of the 16 placebo patients reported a total of 22 adverse reactions; 12 of the 18 diltiazem patients reported a total of 23 adverse reactions (Table VII). Only headache in the placebo group, and dizziness and edema in the diltiazem group, were reported by more than 2 patients. Minor abnormalities in the laboratory values occurred equally in the diltiazem and placebo groups.

Discussion

We investigated the benefits of diltiazem as sole therapy in moderate essential hypertension. Diuretics, β blockers and, to a lesser extent, α blockers have been used as initial therapy in hypertension in spite of significant adverse effects. Diuretics cause impotence, hypokalemia and adverse effects on serum lipids[9] and blood chemistries, as well as possible increased mortality in some groups.[10] Beta blockers impair exercise performance[11,12] and some have adverse lipid effects.[13,14] Paradoxical pressor responses[15] and a fairly high incidence of lack of response are also a problem in using β blockers, as are a number of diseases that contraindicate their use. The α blockers are limited in use because fluid retention, tachycardia and significant orthostatic effects may occur, as well as tachyphylaxis when used as sole therapy.

As shown in the present study, diltiazem does not share these adverse effects, in spite of the fact that upward dose titration was vigorous—up to a daily dosage of 360 mg in all patients. The strict criteria for blood pressure stability in this study were reflected in the lack of placebo response both in terms of mean pressure change and attainment of goal response. In contrast, the diltiazem-treated patients showed a very acceptable response to treatment, with a decrease in average supine blood pressure from 165/100 to 144/87 mm Hg over 12 weeks. At more than an average of 8 months of treatment, average pressure remained at 147/88 mm Hg, but when patients were withdrawn to single-blind placebo, average supine blood pressure rose from 144/84 to 170/100 mm Hg.

Several studies[16–20] of exercise tolerance in hypertensive patients who were treated with various agents (diuretics, methyldopa and β blockers) until normotension was achieved found no significant decrease in exercise tolerance after treatment. Invasive studies,[16,19] however, show that patients receiving β blockers must compensate for decreased inotropy and chronotropy with an increase in stroke volume and arterial-mixed venous oxygen difference, an ability that decreases with age. Bruce et al[16] also showed that the exercise response to treatment was related to the underlying integrity of the recipient's circulatory system.

The studies just mentioned were conducted in patients who were an average of 15 to 20 years younger than those in the present study. The diltiazem-treated group in our study significantly increased maximal exercise duration by 55 seconds ($p < 0.01$), whereas the placebo group exercised an average of 18 seconds more than at baseline (difference not significant). The blunting in heart rate and pressor response to exercise in the diltiazem-treated patients was greater at submaximal than at maximal exercise. The fact that these patients could significantly increase their exercise performance at a mean age >60 years indicates that inotropy was not depressed and that normalized peripheral resistance allowed a ready increase in the stroke volume. Thus, diltiazem appears to normalize the response to exercise (at least with regard to blood pressure) rather than impair it, and may tend to increase exercise tolerance in hypertensive patients as it does in those with angina.[21]

There were no adverse effects on serum glucose, potassium or uric acid levels such as those seen with diuretic administration.

When patients are enrolled in any study of cardiovascular disease, there are often subtle behavioral changes with regard to diet, exercise and other habits, which are difficult to control. However, it does appear that the use of diltiazem is associated with a significant increase in HDL cholesterol in this population. Whether this change is clinically beneficial remains to be seen. It is clear that the adverse lipid effects seen with diuretics and β blockers are not seen with diltiazem. This may reflect a mechanism similar to that responsible for the potentially positive lipid effects of prazosin.[22,23]

Serious adverse reactions to diltiazem were not seen. In consonance with prior experience in the use of diltiazem for the treatment of angina,[24] adverse reactions to diltiazem were quantitatively not very different from those to placebo. Reactions that have been recognized as possibly associated with diltiazem, such as dizziness, edema, constipation and dyspepsia, were neither common nor severe.

When compared with standard therapies for hypertension, such as diuretics and β blockers, diltiazem's major disadvantages are cost and the 2-times-a-day dosage regimen. There are, however, several major advantages: diltiazem shows both short- and long-term effectiveness and is well tolerated; it does not impair exercise performance; it has no adverse effects on blood chemistries; it does not have an adverse effect, and may even have a positive effect, on serum lipids; and it does not cause orthostatic effects, fluid retention or tachycardia. Thus, it can be concluded that diltiazem is an acceptable monotherapy in patients with moderate essential hypertension.

Diuretics Versus Calcium-Channel Blockers in Systemic Hypertension: A Preliminary Multicenter Experience with Hydrochlorothiazide and Sustained-Release Diltiazem

WILLIAM H. FRISHMAN, MD, WALTER KIRKENDALL, MD, JOHN LUNN, MD, DAVID McCARRON, MD, MARVIN MOSER, MD, HAROLD SCHNAPER, MD, L. KENT SMITH, MD, JAMES SOWERS, MD, STEPHEN SWARTZ, MD, and EDWARD ZAWADA, MD

The safety and efficacy of sustained-release diltiazem 120 to 180 mg, 2 times a day, were compared with hydrochlorothiazide 25 to 50 mg, 2 times a day, and the combination of diltiazem and hydrochlorothiazide in 56 patients with mild to moderate hypertension (supine diastolic blood pressure between 95 and 114 mm Hg) using a placebo-controlled, parallel-design protocol. Data from an additional 21 patients were evaluated for safety only. The data reported herein represent the preliminary experience from a larger 200-patient multicenter study. All patients received placebo for 4 weeks, followed by either hydrochlorothiazide or diltiazem titrated to achieve a diastolic blood pressure reduction of ≥10 mm Hg to reach a goal supine diastolic blood pressure of <90 mm Hg. Patients not achieving the treatment goal received hydrochlorothiazide plus diltiazem.

At week 14, on maintenance monotherapy, diltiazem and hydrochlorothiazide produced comparable reductions in blood pressure from placebo baseline (160.3 ± 24.3/101.7 ± 5.5 to 145.2 ± 24.1/89.8 ± 7.4 mm Hg with diltiazem, 156.0 ± 15.6/103.7 ± 4.7 to 134.1 ± 12.5/89.2 ± 9.5 mm Hg with hydrochlorothiazide, p <0.001 for both). Diltiazem and hydrochlorothiazide achieved goal blood pressure in 42% and 45% of patients, respectively. The effects in responders were sustained for 6 months. In patients who did not achieve the treatment goal, 63% responded to diltiazem plus hydrochlorothiazide. No clinically significant postural hypotension was observed on any regimen. Heart rate was slightly lower with diltiazem than with hydrochlorothiazide. Adverse effects were minimal with diltiazem, hydrochlorothiazide and diltiazem plus hydrochlorothiazide but more hypokalemia occurred with hydrochlorothiazide.

Sustained-release diltiazem used twice daily provided safe and effective therapy for mild to moderate hypertension when used alone or in combination with hydrochlorothiazide. As a monotherapy, sustained-release diltiazem is similar in efficacy to hydrochlorothiazide.

Calcium-channel blockers are a distinct group of compounds that interfere with the normal transmembrane flux of extracellular calcium, on which vascular tissue depends for contraction and impulse generation.[1] They reduce the contractile activity of the myocardium and promote coronary and systemic arterial dilation.[1] These hemodynamic effects provide the clinical rationale for the use of calcium-channel blockers in the management of ischemic heart disease[1] and hypertrophic cardiomyopathy.[2]

Because systemic arterial dilation can be expected to reduce elevated arterial blood pressure, there has been considerable enthusiasm for the use of calcium-channel blockers in the medical management of sys-

temic hypertension and hypertensive emergencies.[3–8] The effectiveness and safety of these drugs in the treatment of systemic hypertension have been clearly documented.[3–6,8–13] The efficacy of nifedipine and verapamil appears comparable to that of oral diuretics in hypertension.[3,8,9,14,15] In this report, we describe a preliminary experience from a large multicenter trial designed to be the first well-controlled study comparing sustained-release diltiazem with hydrochlorothiazide in patients with systemic hypertension.

Methods

The data presented are based on a preliminary analysis of 77 patients who are part of a 200-patient multicenter study still in progress.

Patient selection: A total of 77 patients with mild to moderate systemic hypertension were enrolled after written and informed consent was obtained. Fifty-six patients were analyzed for safety and efficacy; 21 for safety only. The demographics of the 56-patient study group are listed in Table I.

All patients who were entered had essential hypertension with a stable resting supine diastolic pressure between 95 and 114 mm Hg while not taking medication. Potential patients were seen before the study, and were entered into a placebo run-in screening phase after all previously administered antihypertensive medication had been stopped for at least 2 weeks. For entry, stable resting supine diastolic pressures (each recorded pressure was the averge of 3 readings using Korotkov phase V) between 95 and 114 mm Hg and varying by $< \pm 7$ mm Hg were required on 2 consecutive weekly visits starting with days 7 to 10 of the placebo run-in screening. If a patient needed more than 4 weeks to stabilize, he or she was considered labile and excluded from further study participation.

Patients with the following conditions were excluded from the study: significant cardiovascular disease other than essential hypertension, impaired renal function, greater than first-degree heart block, sick sinus syndrome, known abuse of alcohol or drugs, pregnancy and known hypersensitivity to thiazides or other sulfonamide-derived drugs.

Experimental design: The design of the multicenter trial is shown in Figure 1. A single-blind, placebo run-in screening of at least 2 weeks was used to establish baseline pressures. Eligible patients were then randomized to treatment with hydrochlorothiazide or sustained-release diltiazem in a double-blind, parallel fashion, using the double-dummy technique. A titration period of up to 2 months then commenced;

TABLE I Demographic Summary

patients were given increasing doses of study medications (240 to 360 mg/day diltiazem; 50 to 100 mg/day hydrochlorothiazide, each in 2 divided doses) until optimal response was reached. Optimal response was either a reduction in supine diastolic blood pressure to <90 mm Hg or a reduction of at least 10 mm Hg for those patients with baseline pressures of 95 to 99 mm Hg. Upon achievement of the optimal response, patients entered an evaluation period for 4 weeks. Patients who achieved and maintained goal pressure reduction with the initial medication remained on that medication and were seen monthly for 3 months.

After the evaluation period, any patient who had not achieved and maintained the goal diastolic blood pressure received the other medication in unblinded fashion (titrated to optimum over a 2-month period) in addition to the initial medication. Upon reaching the optimal dose of the second medication, patients were followed for an additional 1 to 2 months to assess the safety and effectiveness of the combination therapy.

Methods of observation: Resting supine, immediate and 5-minute standing blood pressures were measured 10 to 12 hours after the last dose of medication and before the next dose. Safety was monitored during the placebo and active treatment phases with adverse-effect profiling, electrocardiograms, complete blood counts and blood chemistries.

Statistical analysis: The experiment was designed with stratification by investigator to detect and adjust for any investigator differences in the treatment comparisons. However, because of the imbalance of patient and treatment

* Overall differences between diltiazem and HCTZ therapies.

groups among the various participating medical centers resulting from the interim data, we have simply pooled the sites for this analysis. We have avoided comparison of groups that achieved goal diastolic blood pressure on monotherapy with groups that did not achieve goal on combined therapy because of possible confusion in interpretation due to the different selection processes of these groups.

Baseline comparisons were made to test for differences in the treatment groups. For the parameters of sex, race, age, classification and smoking status, Fisher's exact test for 2 × 2 tables was used. For the parameters of duration of hypertension, diastolic blood pressure, systolic blood pressure, mean arterial pressure and heart rate, a *t* test for independent samples was used.

Fisher's exact test for independence using 2 × 2 tables was used to analyze diastolic blood pressure goal achievement by comparing (1) diltiazem with hydrochlorothiazide at week 14, (2) diltiazem blood pressure-goal achievers on monotherapy with hydrochlorothiazide-goal achievers on monotherapy at week 26 and (3) diltiazem-non-goal achievers on combined therapy with hydrochlorothiazide-non-goal achievers on combined therapy at week 26.

The *t* tests were then used to analyze the mean change by treatment in supine, immediate and 5-minute standing systolic and diastolic blood pressures, mean arterial pressure and heart rate. Analysis-of-variance methods, accounting for between- and within-patient variability, were used to compare (1) diltiazem with hydrochlorothiazide up to week 14, (2) diltiazem-goal achievers on monotherapy with hydrochlorothiazide-goal achievers on monotherapy over weeks 14, 18, 22 and 26 and (3) diltiazem-non-goal achievers on combined therapy with hydrochlorothiazide-non-goal achievers on combined therapy over weeks 14, 22 and 26. Comparisons between hydrochlorothiazide and diltiazem were made dependent on a check for treatment-by-evaluation interaction. If the interaction was significant, comparisons were made and reported at each evaluation. If the interaction was not significant, an overall treatment main-effect comparison, which averages over evaluations, was reported. In addition, a covariance analysis on the week 14 data was used to check for response differences because of other identifiable factors, including age and race.

To evaluate the potential for postural hypotension, differences between immediate standing and resting supine systolic and diastolic blood pressures, mean arterial pressure and heart rate were examined. Analysis-of-variance tests of these differences were used to compare (1) diltiazem with hydrochlorothiazide over baseline and week 14, (2) diltiazem-goal achievers on monotherapy with hydrochlorothiazide-goal achievers on monotherapy over weeks 14 and 26 and (3) diltiazem-non-goal achievers on combined therapy over weeks 14 and 26. These evaluations were made for each group in total, as well as for subsets of each group based on age.

Results

A total of 77 patients were enrolled; 56 could be evaluated for both safety and efficacy. The other 21 patients could not be analyzed for the following reasons: inability to tolerate medications (7); noncompliance with dosing instructions (7); and withdrawals for other reasons, including protocol violations and other illness (7). The data from these patients are included in the safety analysis.

Blood pressure and heart rate: Both diltiazem and hydrochlorothiazide caused a significant reduction in systolic and diastolic blood pressures at week 10 (end of titration) and at week 14 (end of maintenance). The data for supine, immediate and 5-minute standing systolic, diastolic and mean blood pressures and heart rate are shown in Tables II through V. At week 14, the mean daily dose of diltiazem was 326 mg; for hydrochlorothiazide it was 79 mg.

The ability of diltiazem and hydrochlorothiazide to produce the goal reduction in supine and diastolic blood pressure was compared at week 14. Diltiazem produced the goal in 42% and hydrochlorothiazide in 45% of patients. In the patients maintained on diltiazem and hydrochlorothiazide monotherapy beyond week 14, the effects of therapy on blood pressure were maintained (observed at weeks 18, 22 and 26). At week 26, 91% of patients on diltiazem who achieved goal blood pressure at week 14 had maintained the goal pressure, while 73% of patients on hydrochlorothiazide maintained the goal blood pressure reduction.

The addition of hydrochlorothiazide to patients receiving diltiazem who did not achieve the goal pressure reduction at week 14 produced the goal pressure reduction in 6 of 11 patients (55%) at week 26. The addition of diltiazem to patients receiving hydrochlorothiazide who did not achieve the goal blood pressure at week 14 produced the goal pressure reduction in 10 of 14 patients who completed the study (71%).

Safety: Significant postural drops in blood pressures were not seen with either diltiazem or hydrochlorothiazide treatment. Significant adverse effects were minimal for diltiazem, hydrochlorothiazide and the combination. Four patients on diltiazem, 5 on hydrochlorothiazide and none on the combination discontinued participation because of adverse effects. No significant electrocardiographic abnormalities were noted. No significant alterations in laboratory values, other than those alterations in electrolytes consistent with thiazide therapy, were seen. Specifically, 7 patients became hypokalemic and 4 patients developed hyperuricemia on hydrochlorothiazide alone. On combination diltiazem and hydrochlorothiazide, the pattern was similar to that of hydrochlorothiazide alone: 8 patients developed hypokalemia and 7 patients developed hyperuricemia.

Discussion

Many of the calcium-channel blockers have been shown to be safe and effective for the treatment of systemic hypertension and hypertensive emergencies.[3–6,8–13,16,17] In this preliminary report of a large study of 200 patients, sustained-release diltiazem used twice daily was shown to be as effective as hydrochlo-

rothiazide used twice daily in reducing supine and standing blood pressure, both short and long term, in patients with mild to moderate systemic hypertension. Diltiazem was shown to cause a small but clinically insignificant reduction in heart rate compared with hydrochlorothiazide; whereas in the doses used, hydrochlorothiazide caused more hypokalemia. Both drugs were well tolerated.

Although diltiazem and hydrochlorothiazide are equally effective in the treatment of hypertension, they have different hemodynamic and metabolic effects (Table VI).[16,18–20] Diltiazem reduces blood pressure predominantly through its vasodilator actions, without causing tachycardia.[3,9] Calcium entry blockers have also been shown to have natriuretic effects.[16] They do not affect blood sugar, uric acid, lipids or potassium levels. Diuretics, such as hydrochlorothiazide, work initially by reducing intravascular volume and cardiac output; later, with physiologic adaptations to therapy, vascular volume returns to baseline, vascular resistance is reduced and cardiac output is maintained. Diuretics raise plasma renin activity and, unlike diltiazem, can cause hyperglycemia in type II diabetic patients, raise plasma lipids and uric acid and reduce serum potassium.[21,22]

With long-acting, sustained-release preparations now available, diltiazem and some other calcium-channel blockers can be considered first-line therapy and alternative therapy to β blockers and diuretics because of their favorable hemodynamic and metabolic characteristics and low adverse-effect profiles. They may become the treatment of choice in patients with hypertension and angina pectoris, for which they have proven efficacy.[23,24] Among the calcium-channel blockers, diltiazem has one of the lowest adverse effect frequencies[5] and should play an important role in the treatment of hypertension in years to come.

Implications: These preliminary findings confirm that sustained-release diltiazem is an effective agent in systemic hypertension with an antihypertensive potency similar to that of diuretics. Diltiazem has similar antihypertensive effects on other calcium-channel blockers. Because of the minimal adverse effects usually encountered with diltiazem and its intrinsic negative chronotropic action, it is likely to be useful as a single-drug treatment for hypertension. However, the higher cost of diltiazem and other calcium-channel blockers, compared with diuretic agents, may limit their use to patients in whom advantages in efficacy, adverse effect-profiles or compliance are shown.

Antihypertensive Therapy with Calcium-Channel Blockers: Comparison with Beta Blockers

BARRY M. MASSIE, MD

As a result of concern about the safety and long-term toxicity of diuretics, there is a growing trend toward the use of alternative agents as initial therapy in essential hypertension. Worldwide, β blockers and vasodilators, especially the calcium-channel blockers, are the most commonly used alternative agents. Several studies comparing these 2 classes of medications are reviewed. These studies indicate that verapamil, nifedipine and diltiazem are all comparable in efficacy to β blockers. When combined, calcium-channel blockers and β blockers produce additive responses. These agents may differ in the relation between the magnitude of their antihypertensive effect and patients' pretreatment plasma renin activity and age. Younger persons and those with high plasma renin activity tend to respond better to β blockers; older subjects and those with low plasma renin activity are more consistently responsive to calcium-channel blockers. The choice of agent should be individualized, based upon accompanying illnesses, adverse-effect profile and demographic factors.

(Am J Cardiol 1985;56:97H–100H)

Although the Joint National Committee on the Detection, Evaluation and Treatment of High Blood Pressure continues to recommend diuretics as the initial therapy in essential hypertension,[1] there is a growing trend toward the use of alternative agents. The main impetus for this shift has been increasing concern about the safety and long-term toxicity of diuretics. The electrolyte and metabolic derangements induced by diuretics have been recognized for many years. The suggestion, albeit poorly substantiated, from the Multiple Risk Factor Intervention Trial that diuretic therapy may be associated with an excessive incidence of sudden death[2] and the difficulty of demonstrating a decrease in coronary mortality despite successful antihypertensive therapy in several large trials using diuretics have accentuated these doubts.

A second reason for modifying the stepped-care approach is that patients with mild or moderate hypertension who are not controlled by diuretics alone may be controlled by other agents and, therefore, alternative drugs should be evaluated before resorting to combination therapy.[3] A third factor to consider is individualization of therapy in patients with multisystemic disease. Accordingly, a β blocker might be used in patients with hypertension and angina and prazosin might be tried in competitive athletes, while diuretics would be avoided in patients with gout or diabetes. Finally, the reduction in mortality and, in some instances, reinfarction by β blockers in secondary prevention trials[4,5] has encouraged many physicians to use these agents in hypertension with the hope that they are similarly effective in primary prevention, although evidence for this is lacking.

In the United States, β blockers are the most popular alternative to diuretics, and their use as initial therapy has been sanctioned by the Joint National Committee.[1] In Europe, the calcium-channel blockers are widely used as initial antihypertensive therapy. These agents have not yet been approved in the U.S. for this indication by the Food and Drug Administration, but marketing surveys suggest they are used widely in hypertension, nonetheless. This article will review studies in which these 2 classes of medications have been compared or used in combination therapy and it will attempt to place their use into a broader perspective.

Verapamil

Verapamil was the first calcium-channel blocker used in hypertension, and several trials comparing verapamil with β blockers have been published. Leonetti et al[6] evaluated 31 patients with mild to moderate hypertension who were withdrawn from previous therapy, and randomized to either propranolol, 60 to 80

From the Cardiology Service, Veterans Administration Medical Center, and the Department of Medicine and Cardiovascular Research Institute, University of California, San Francisco, California.

mg, 3 times a day, or verapamil, 120 to 180 mg, 3 times a day, for 6 weeks. Then, after a 3-week washout period, patients were crossed over to the alternative drug. Verapamil produced a somewhat greater reduction in both systolic and diastolic pressures than propranolol (31/20 vs 17/17 mm Hg), but this difference was not statistically significant. Heart rate fell significantly (by 14 beats/min) on propranolol, but not on verapamil (insignificant decrease of 3 beats/min). Hornung et al[7] evaluated the same 2 agents with interarterial pressure monitoring. Eighteen subjects completed an open-label, randomized crossover study in which propranolol and verapamil were titrated from 40 to 240 mg, 2 times a day, and 120 to 240 mg, 2 times a day, respectively, over 2 to 3 months. Both drugs produced similar antihypertensive responses, which were present at rest and during exercise. In addition, no differences in the 24-hour blood pressure profiles were noted. The frequency and severity of adverse effects were similar, with constipation predominating on verapamil and fatigue on propranolol.

Doyle[8] reported 2 studies—one comparing verapamil with pindolol in patients maintained on thiazide diuretics and the second comparing verapamil with labetalol in patients with coexisting chronic obstructive pulmonary disease. Both trials indicated that the 2 classes of drugs caused equivalent antihypertensive responses.

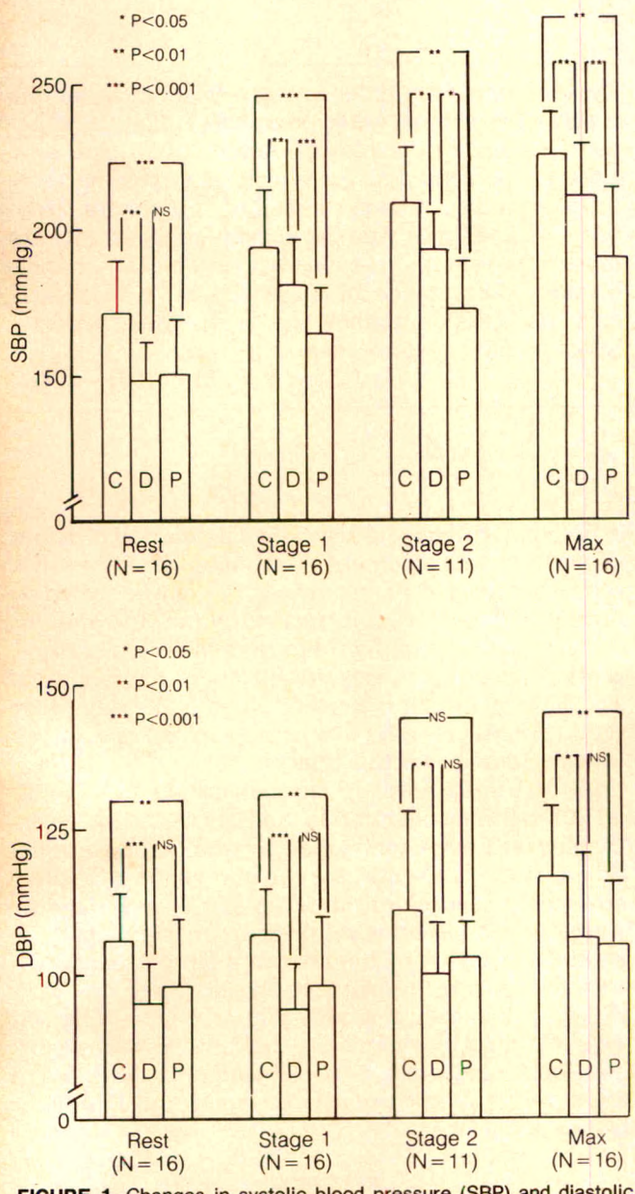

FIGURE 1. Changes in systolic blood pressure (SBP) and diastolic blood pressure (DBP) during treatment with placebo (C), diltiazem (D) 60 mg, 3 times a day, and propranolol (P) 20 mg, 3 times a day. The findings at rest, during submaximal exercise at the same workload (stages 1 and 2) and during maximal exercise (Max) are shown. Both drugs produced comparable responses at rest and during exercise in DBP, but propranolol was more effective in blunting the exercise-induced rise in SBP. NS = difference not significant. Reprinted with permission from Am J Cardiol.[13]

Nifedipine

Ekelund et al[9] performed an open-label trial in which 12 patients received placebo, nifedipine alone, nifedipine plus metoprolol and metoprolol alone for consecutive 1-month periods. Blood pressure was measured at rest and during exercise. Nifedipine decreased supine systolic and diastolic pressures by 20 and 11 mm Hg, respectively, compared with 22 and 7 mm Hg with metoprolol (differences not significant). During exercise, however, systolic blood pressure fell further with metoprolol than with nifedipine (39 vs 14 mm Hg). Both at rest and during exercise, nifedipine produced a slight increase in heart rate, while metoprolol significantly lowered it. Combined therapy was significantly better than single therapy, both at rest and during exercise.

Yagil et al[10] conducted a 2-phase study in which 26 severely hypertensive subjects (mean blood pressure 192/114 mm Hg on propranolol) were on a regimen consisting of nifedipine 10 to 30 mg, 3 times a day, added to propranolol. After a 14- to 30-week period of combined therapy (phase I), nifedipine and propranolol were alternatively withdrawn for 2- to 4-week periods, separated by a similar period in which the combination was reinstituted. The addition of nifedipine (mean dosage 60 mg/day) was highly efficacious, resulting in a sustained decrease in blood pressure from 189/112 to 136/84 mm Hg. During phase II, blood pressure was found to increase to pre-nifedipine levels when this drug was withdrawn. Propranolol withdrawal also resulted in a loss of control, but the blood pressure increase was significantly less than that during nifedipine withdrawal. It is noteworthy that adverse effects related to nifedipine occurred in 50% of the patients and necessitated discontinuation in 4 patients.

Two additional studies[11,12] evaluated acebutalol and nifedipine, alone and in combination, and pindolol and nifedipine, also in single and combined therapy. While both studies are limited by small numbers of patients, they each indicated equal antihypertensive efficacy for both classes of drugs, as well as added benefit from combination therapy.

Diltiazem

Diltiazem, because of its more recent development and availability, has been less widely studied in hyper-

tension. Nonetheless, there are 2 published trials, and preliminary findings from an ongoing multicenter study comparing this agent with β blockers are available. Yamakado et al[13] treated 16 subjects with mild to moderate hypertension with placebo, propranolol 20 mg, 3 times a day, and diltiazem 60 mg, 3 times a day, for 4 weeks, using a Latin square design. Resting and treadmill exercise blood pressures were evaluated (Fig. 1). At rest, both agents lowered blood pressure comparably, from a mean of 171/106 to 148/95 mm Hg with diltiazem and to 150/98 mm Hg with propranolol. Heart rate fell from 76 to 70 beats/min with diltiazem and to 59 beats/min with propranolol. During exercise, both drugs lowered diastolic pressure to a similar degree, but propranolol decreased systolic pressure somewhat more than diltiazem and caused a greater reduction in maximal heart rate. No adverse effects were noted, but the dosages of both drugs were relatively low.

Trimarco et al[14] compared diltiazem 60 mg, 4 times a day, with metoprolol 100 mg, 2 times a day, in 20 patients using a randomized, double-blind crossover design with 1-month treatment periods separated by a 1-month placebo period. Both drugs produced comparable antihypertensive effects, although metoprolol was more effective in preventing an increase in exercise systolic pressure. Only metoprolol reduced heart rate.

A multicenter trial comparing diltiazem with other agents is now in progress and will ultimately include 200 patients, thus permitting subgroup analysis based upon age and race. At present, only the findings from an interim analysis of the first 50 subjects who completed the study are available. The study design includes a 4-week, single-blind, placebo washout period, after which the patients are randomly assigned to double-blind treatment with diltiazem or propranolol. The first 3 months are a dose-titration phase in which the diltiazem dosage (in time-released form) is increased from 60 to 160 to 180 mg, 2 times a day, and propranolol is increased from 80 to 120 to 240 mg, 2 times a day, stepwise at monthly intervals. After 4 weeks at the titrated dosage, hydrochlorothiazide is added to the therapy of uncontrolled patients for an additional 8 weeks. Sixty percent of the diltiazem group and 44% of the propranolol group required the highest dose, and 32% and 40%, respectively, ultimately required the addition of diuretic. With this therapy, 59% of the diltiazem patients and 40% of the propranolol patients achieved the predetermined treatment goal of a supine diastolic blood pressure <90 mm Hg, or, in those with initial diastolic pressure of 95 to 100 mm Hg, a minimum of a 10-mm Hg reduction. In the diltiazem group, the mean supine blood pressure fell from 148 ± 17/101 ± 5 pretreatment to 133 ± 25/88 ± 9 mm Hg ($p < 0.0001$); in the propranolol group, a comparable reduction occurred from 154 ± 22/104 ± 6 to 146 ± 23/91 ± 11 mm Hg. Heart rate fell from 81 ± 24 to 74 ± 11 beats/min ($p < 0.01$) with diltiazem and from 77 ± 8 to 64 ± 11 beats/min ($p < 0.0001$) with propranolol; this was the only significant difference between treatments. The addition of hydrochlorothiazide produced a further decrease of 8 to 12 mm Hg in systolic and diastolic pressures in both treatment groups. Adverse effects and adverse reactions were generally mild and were slightly more common on propranolol (34%) than diltiazem (25%).

Calcium-Channel Blockers and Beta Blockers in Patients with Angina and Hypertension

In the U.S., calcium-channel blockers are currently used to treat hypertension primarily in patients with accompanying coronary artery disease. Frishman et al[15] studied 12 such patients with stable angina pectoris, positive treadmill exercise test results and diastolic blood pressure >90 mm Hg. After a 2-week washout period, double-blind treatment was commenced with verapamil 80 mg, 3 times a day, or propranolol 20 mg, 3 times a day, with the dosage being increased at weekly intervals to 120 mg, 4 times a day, and 80 mg, 4 times a day, respectively. The two 3-week treatment periods were separated by a 1-week placebo period. The 2 drugs produced comparable changes in blood pressure, but propranolol reduced heart rate significantly more. Both drugs reduced the frequency of anginal attacks, but exercise duration increased significantly on verapamil despite a lower rate-pressure product with propranolol.

Factors Determining the Response to Calcium-Channel Blockers and Beta Blockers

From these studies, it is apparent that both the calcium-channel blockers and β blockers are effective antihypertensive agents. Bühler et al[16] have examined the response of a large number of patients in relation to the pretreatment plasma renin activity. Their findings confirm previous reports that β blockers are most effective in high renin hypertension. In contrast, they found that calcium-channel blockers are particularly potent in low renin hypertension. Clinically, these observations are most relevant in regard to age, because younger patients tend to have higher plasma renin activity, while older patients often have low plasma renin activity. Indeed, Bühler's experience corroborates the greater efficacy of calcium-channel blockers in the elderly and β blockers in younger subjects (Fig. 2). Data are not yet available for the relative response rates of these 2 classes of agents in blacks, who usually have low plasma renin activity, and whites, who exhibit a wider spectrum of plasma renin activity.

More Trials Needed

Because of the small size of the reviewed trials, further information is needed on a number of important points. Definitive data concerning the relative efficacy of the 2 classes of agents in subgroups based on gender, race and age might help in the selection of therapy. Similar information concerning adverse effects may be equally valuable. Beta blockers have been associated with potentially adverse effects on serum lipids; calcium-channel blockers have not. Nonetheless, it would be informative to examine these measurements in a prospective comparative trial involving the same patient population and laboratory.

The greatest differences between the responses to calcium-channel blockers and β blockers in the published trials were in exercise heart rate and systolic

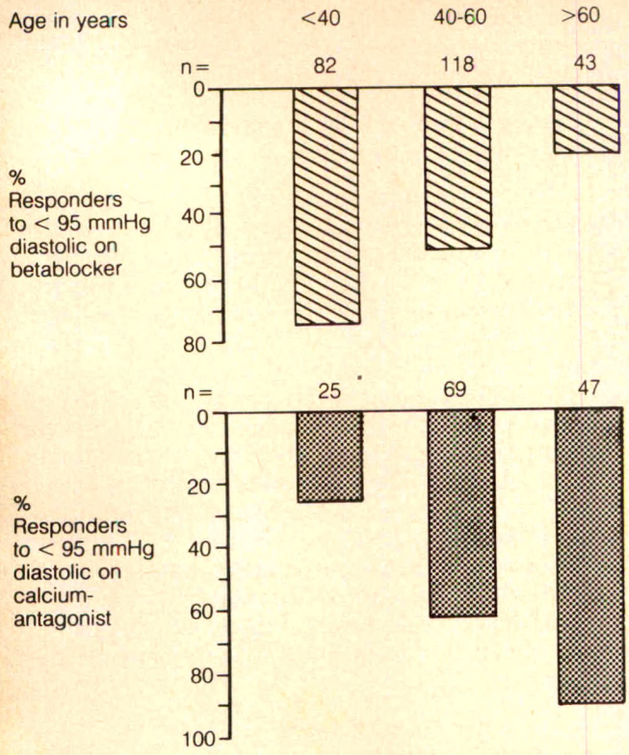

FIGURE 2. Proportion (%) of patients responding with diastolic blood pressure reduction to ≤95 mm Hg during antihypertensive therapy with β blockers and calcium-channel blockers according to their age. Reprinted with permission from Am J Med.[16]

blood pressure, which rose to a lesser extent on the latter agents. It would be interesting, then, to determine whether this is associated with actual differences in exercise performance. None of the published studies addressed this issue by measuring oxygen utilization, and several did not use the appropriate protocols to examine this question.

Clinical Implications

The studies reviewed herein indicate that the calcium-channel blockers are as effective in treating mild and moderate hypertension as β blockers, and in the case of diltiazem, they are equally or better tolerated. Because of concerns about the safety of diuretics, both classes of agents are commonly used as initial therapy in Europe. The choice of which type of medication to use in individual patients should reflect demographic factors, the patient's life-style and the nature of accompanying medical problems. Thus, in older patients calcium-channel blockers may be the most effective alternative to diuretics, whereas in young patients a β blocker or converting enzyme inhibitor should be considered. Blacks may be more responsive to calcium-channel blockers than to β blockers, although this remains to be demonstrated. When mental activity or athletic performance is an issue, calcium-channel blockers may be preferable to β blockers, because they have few central nervous system effects and they are likely to have less of a depressant effect on maximal cardiac output, although the latter point has not been investigated at the high dosages used in antihypertensive therapy or in competitive athletes. Patients with bronchospastic conditions, peripheral vascular disease, insulin-dependent diabetes and left ventricular dysfunction may be appropriate candidates for calcium-channel blockers, while those predisposed to postural symptoms or edema are better candidates for β blockers. Combination therapy with nifedipine and β blockers is safe and effective, but more experience is needed with diltiazem. Beta blocker and verapamil combinations should not be used in this way for hypertension because of the potential for atrioventricular block, bradyarrhythmias or myocardial depression.

Several additional factors will determine the future role of calcium-channel blockers in the treatment of hypertension, including their place relative to β blockers and diuretics. These include approval from the Food and Drug Administration for this indication, their relative cost, which is presently significantly higher than other antihypertensive agents, and the availability of twice-daily—or better still, once-daily—preparations. Finally, clarification of the safety of diuretics and determination of whether the calcium-channel blockers are cardioprotective will enormously influence their ultimate popularity.

Comparative Effects of Diltiazem and Hydrochlorothiazide in Blacks with Systemic Hypertension

MARVIN MOSER, MD, JOHN LUNN, MD, and BARRY J. MATERSON, MD

The blood pressure-lowering effects of a calcium-entry blocker, diltiazem (240 or 360 mg/day), and a thiazide diuretic, hydrochlorothiazide (50 or 100 mg/day), were studied in 20 black hypertensive patients. Supine blood pressure decreases of −34/−18 mm Hg for diltiazem and −29/−21 mm Hg for hydrochlorothiazide were noted after 14 weeks of therapy. Differences between drugs were not significant. Blood pressures were normalized in all 4 of the monotherapy nonresponders when the 2 drugs were combined. Significant adverse effects were not noted.

These data suggest that diltiazem is an effective antihypertensive agent in black patients. As monotherapy, its blood pressure-lowering effect is equivalent to hydrochlorothiazide.

(Am J Cardiol 1985;56:101H–104H)

Studies have shown that black patients respond more effectively to some antihypertensive agents than to others.[1–7] This suggests the need to evaluate the effectiveness of new antihypertensive agents in black patients. Calcium-entry blockers are among the newer drugs being evaluated as antihypertensive agents. Although these agents have not yet been approved for therapy in the United States, there have been numerous reports suggesting that they are effective as blood pressure-lowering medications.[8–10]

This study was part of a multicenter trial designed to compare the antihypertensive effectiveness of diltiazem, a calcium entry–blocking agent, with hydrochlorothiazide, a thiazide diuretic, as monotherapy in patients with mild to moderate hypertension. In addition, the study assessed the effectiveness of combined therapy with both diltiazem and hydrochlorothiazide in patients who did not achieve goal blood pressure on monotherapy.

Data are reported on 20 black patients, followed for a 6-month period, on either monotherapy or combined therapy. This review includes efficacy and adverse effect data relating to therapy with both drugs.

Methods

Study design: Patients were initially evaluated in a placebo screening phase of at least 2 weeks, after a 2-week abstinence from any previous antihypertensive drug therapy or other medication known to affect blood pressure. A resting supine diastolic blood pressure of 95 to 114 mm Hg, not varying by >7 mm Hg, was required on 2 consecutive weekly visits for inclusion in the study. Baseline measurements for diastolic and systolic blood pressure and heart rate were obtained by averaging the readings taken on the last 2 visits of the placebo screening phase. Mean arterial blood pressure was then calculated from the observed diastolic and systolic blood pressure. Conduction intervals (from electrocardiogram) and automated blood chemistries, including serum lipid levels, blood counts and urinalyses, were obtained at baseline and at the end of the study.

Patients were assigned to either sustained-release diltiazem or hydrochlorothiazide in a randomized, double-blind parallel design. Titration to 240 or 360 mg of diltiazem or 50 or 100 mg of hydrochlorothiazide was carried out over an 8-week period (through week 10 of the study). Monotherapy effects were observed over 4 additional weeks (through week 14). Blood pressure measurements were obtained approximately 12 hours after the last dose of medication.

Goal blood pressure was defined as a supine diastolic blood pressure <90 mm Hg if baseline supine diastolic blood pressure was ≥100 mm Hg, or at least a 10-mm Hg supine diastolic blood pressure reduction if baseline supine diastolic blood pressure was <100 mm Hg. At week 14, those patients who had achieved goal blood pressure were continued on the assigned monotherapy, either diltiazem or hydrochlorothiazide, for an additional 12 weeks. If a patient had not achieved goal by week 14, he or she was "unblinded" and the alternate drug was added to the original regimen for an additional 12 weeks. The study was designed to simulate a clinical situation in which additional therapies are added if monotherapy is ineffective.

Three groups resulted for analysis: subjects who achieved goal blood pressure with diltiazem and who continued on diltiazem; subjects who achieved goal with hydrochlorothiazide and continued on hydrochlorothiazide; and subjects

TABLE I Characteristics of Study Patients

	Diltiazem	Hydrochlorothiazide
Male (n)	0	2
Female (n)	10	8
Average age (years)	54.9 ± 10.4	54.3 ± 9.3
Weight (lb)	156.9 ± 22.3	173.3 ± 33.1
Supine DBP (mm Hg)	104.5 ± 3.0	103.4 ± 4.1
Supine SBP (mm Hg)	165.4 ± 17.9	154.6 ± 10.9
Supine MAP (mm Hg)	124.8 ± 6.3	120.5 ± 5.6
Supine HR (beats/min)	76.9 ± 8.1	73.2 ± 9.7
Standing DBP (mm Hg)	102.0 ± 4.8	102.0 ± 6.1
Standing SBP (mm Hg)	158.1 ± 19.0	144.0 ± 9.1
Standing MAP (mm Hg)	120.7 ± 8.6	116.0 ± 5.4
Standing HR (beats/min)	80.7 ± 7.7	76.6 ± 10.5

DBP = diastolic blood pressure; SBP = systolic blood pressure; MAP = mean arterial pressure; HR = heart rate.

who did not achieve goal with either diltiazem or hydrochlorothiazide and were consequently followed on combination therapy. (Two patients were continued on monotherapy, 1 on each drug, beyond week 14 even though goal blood pressure was not achieved.)

Standard statistical methods (paired *t* test, analysis of variance, Fisher's exact test) were used to determine significance of blood pressure decreases and goal responders for the 2 monotherapy groups at 14 weeks. Analysis at week 26 included a comparison of 3 groups: those receiving diltiazem only, those receiving hydrochlorothiazide only and those receiving both drugs.

Results

Table I summarizes the demographics and baseline blood pressures in the 2 groups of patients receiving monotherapy. Mean blood pressures were somewhat higher in the group randomized to diltiazem.

Table II summarizes the number and percentage of patients achieving goal pressures on monotherapy and combined therapy. At week 14, 7 of 9 patients responded to diltiazem alone and 6 of 10 patients had reached goal with hydrochlorothiazide (differences not significant). At week 26, 6 of 8 patients on diltiazem were at goal pressure, whereas all patients on hydrochlorothiazide or receiving combined therapy had achieved goal pressure.

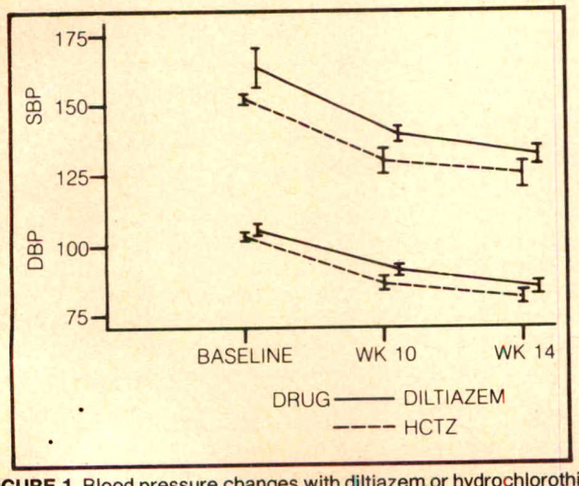

FIGURE 1. Blood pressure changes with diltiazem or hydrochlorothiazide (HCTZ) as monotherapy. All patients were in resting supine position. DBP = diastolic blood pressure; SBP = systolic blood pressure.

Table III summarizes supine blood pressure changes in *all patients* on monotherapy at weeks 10 and 14. A decrease of −34/−18 mm Hg from baseline was noted at week 14 with diltiazem, and a decrease from baseline of −29/−21 mm Hg with hydrochlorothiazide. These are equivalent clinical responses, showing no statistically significant differences. Figure 1 shows blood pressure differences noted over the course of the study with both drugs.

Results of supine blood pressure changes in the *goal achievers* on hydrochlorothiazide or diltiazem monotherapy over the 6-month duration of the study are noted in Table IV. Initial decreases in pressures from baseline to week 14 were −32/−19 mm Hg for diltiazem and −35/−27 mm Hg for hydrochlorothiazide. These responses were maintained with only slight changes for the duration of the study (through week 26). Again, there were no statistically significant differences between drugs.

The 4 patients requiring combination diltiazem and hydrochlorothiazide after week 14 achieved an additional blood pressure response of −11/−10 mm Hg at week 26 (Table V). All of these patients achieved goal response.

Upright blood pressure responses (immediately upon standing and 5 minutes after standing) were essentially similar to those noted in the supine position. At week 14, patients taking diltiazem showed a greater blood pressure decrease on standing than did those taking hydrochlorothiazide. The increases seen in heart rate on standing in the respective drug groups were not significantly different.

Electrocardiogram analysis: Electrocardiograms were taken during the first preplacebo visit and at 26 weeks, and were examined for changes in PR, QRS and QT intervals. Although the differences found are probably not of clinical significance, the diltiazem monotherapy group showed a statistically significant decrease in the QRS interval from 0.077 to 0.065 seconds at week 26 and a statistically significant increase in QT interval from 0.37 to 0.39 seconds. The combination therapy group showed a statistically significant increase in PR interval from 0.19 to 0.20 seconds. No other significant changes were noted.

Adverse effects: Patients reported few adverse effects throughout the study. One patient receiving diltiazem complained of a headache, which resolved with continued therapy. The laboratory findings on diltiazem showed no significant effects on serum electrolyte levels. Serum potassium levels decreased from a mean of 4.1 to 3.9 mEq/liter and uric acid levels increased from 5.1 to 5.6 mg% in the hydrochlorothiazide group. Statistically significant changes in lipid levels were not noted with either drug, although cholesterol levels decreased over the course of the study with both drugs (263 to 235 mg% with diltiazem, and 231 to 204 mg% with hydrochlorothiazide).

Discussion

Previous studies have demonstrated that black patients do not respond as well as whites to propranolol,[1] nadolol,[2] atenolol,[3] pindolol[4] or captopril.[5–7] In each of the above trials, blacks responded as well as or better

TABLE II Number of Patients Achieving Goal Blood Pressure

	Week 10	Week 14		Week 22	Week 26
Diltiazem	4 of 10 (40%)	7 of 9 (78%)	Diltiazem only	4 of 8 (50%)	6 of 8 (75%)
			Hydrochlorothiazide and Diltiazem	2 of 4 (50%)	4 of 4 (100%)
Hydrochloro-thiazide	5 of 10 (50%)	6 of 10 (60%)			
			Hydrochlorothiazide only	7 of 7 (100%)	7 of 7 (100%)

TABLE III Supine Blood Pressure (mm Hg) Changes in All Patients on Monotherapy with Diltiazem or Hydrochlorothiazide*

	Baseline	Week 10	Week 14	Difference (Baseline − Week 14)
Diltiazem	165/104	140/91	133/86	−34 (p = 0.0002) −18 (p = 0.0001)
Hydrochloro-thiazide	154/103	129/87	125/82	−29 (p = 0.0003) −21 (p = 0.0002)

* There were no statistically significant differences between drugs.

TABLE IV Supine Blood Pressure (mm Hg) in Responders After Monotherapy with Diltiazem or Hydrochlorothiazide*

	Baseline	Week 14	Week 26	Difference (Baseline − Week 26)	Difference (Week 14 − Week 26)
Diltiazem	166/105	134/86	138/85	−28 (p = 0.0051) −20 (p = 0.0001)	+4 (NS) −1 (NS)
Hydrochloro-thiazide	156/105	121/78	125/81	−31 (p = 0.0027) −23 (p = 0.0001)	+4 (NS) +3 (NS)

* There were no statistically significant differences between drugs.
NS = not significant.

than whites to hydrochlorothiazide, chlorthalidone and bendroflumethiazide. When any 1 of these diuretics was combined with propranolol, nadolol or captopril in these studies, the racial differences were abolished and goal blood pressure responses were noted in a high percentage of patients.

Labetalol[11] appears to work as well in blacks as in whites. Data indicate that nitrendipine,[12] a new calcium-entry blocker related to nifedipine, is also effective in black patients. The present study suggests that there is little difference in the blood pressure response in blacks between hydrochlorothiazide in dosages of 50 or 100 mg and diltiazem in dosages of 240 or 360 mg/day when given as monotherapy. Further, the magnitude of blood pressure reduction was significant, and goal blood pressure was achieved in a majority of patients.

It has been suggested that baseline renin status or the relative levels of activity of the kinin or other vasodilator systems may play a role in and at least partially explain the racial differences in response to different antihypertensive medications. Beta-adrenergic inhibitors and converting enzyme inhibitors[13] are less effective in patients with low baseline plasma renin levels, and hypertensive blacks as a group tend to have lower plasma renin activity than whites. Black patients also tend to have a less active kinin system. Labetalol, an α antagonist as well as a β-adrenergic blocking agent, may be less affected by renin status, and the action of diltiazem and other calcium-entry blockers, by virtue of their direct vasodilating effects, may also be less influenced by the activity of the renin-angiotensin system. It has also been suggested that calcium-entry blockers are more effective in the elderly, another group of patients in whom resting low renin levels are noted with relatively high frequency.

Blaustein and Hamlyn[14] have offered a unifying hypothesis for sodium-calcium exchange and hypertension based on natriuretic hormones. This predicts that blacks and other patients with low renin hypertension would respond particularly well to calcium-entry blockers.

A preliminary report[15] suggests that methyldopa is effective in reducing the blood pressure of black patients who have an increase ≥5 mm Hg in diastolic blood pressure upon standing. Fifteen of 23 patients with an orthostatic increase showed a reduction of 15.4 ± 12.2 compared with only 1.6 ± 11.5 mg Hg for those 8 without an orthostatic increase. The dosage ranged from 250 to 1,000 mg, 2 times a day. Hydrochlorothiazide at 25 to 50 mg, 2 times a day, achieved a greater overall quantitative blood pressure reduction (−17 vs −11 mg Hg), but results did not correlate with orthostatic change. This suggests that differences in base-

TABLE V Supine Blood Pressure (mm Hg) in Nonresponders After Combined Therapy (Diltiazem and Hydrochlorothiazide)

Week 14 (End of Monotherapy)	Week 26	Difference (Week 14 − Week 26)
138	127	−11 (p = 0.0502)
92	82	−10 (p = 0.0042)

line sympathetic tone in black patients could account for differences in response and might explain some of the differences among studies.

The reasons for the observed racial differences in response to various drugs have not been identified with certainty. Multiple factors are likely to be responsible and they have been reviewed elsewhere.[1,16]

Whatever the underlying mechanisms, physicians should be aware of the potentially different effects of antihypertensive agents in different racial groups. A more rational approach to therapy may therefore be planned. The present study comparing the blood pressure-lowering effects of diltiazem and hydrochlorothiazide in a small group of black patients suggests that an equivalent response can be expected when the drugs are used as monotherapy. An additional blood pressure-lowering effect occurs when the drugs are combined in standard clinical dosages.

In summary, diltiazem at 240 or 360 mg/day appears to be as effective an antihypertensive agent as hydrochlorothiazide at 50 or 100 mg/day in black patients with mild to moderately severe hypertension. There were no significant blood pressure differences between the 2 drugs as monotherapy when changes from baseline were compared at the end of week 14 and week 26. When the 2 drugs were combined in those who did not respond to monotherapy, a further statistically significant decrease in blood pressure was obtained. These data suggest that diltiazem as monotherapy is an effective antihypertensive agent in black patients and may also be useful in combination with a diuretic. Significant adverse effects were not noted with either drug, but diltiazem produced a greater decrease in standing blood pressure. There was no evidence that diltiazem alone adversely affected cardiac conduction or arrhythmias, although a statistically significant increase in QT interval was noted (0.02 seconds). PR interval was slightly increased in the group receiving both drugs (0.01 seconds).

Individualization of Calcium Entry–Blocker Dosage for Systemic Hypertension

ROBERT W. PIEPHO, PhD

The calcium entry blockers are used in a wide variety of clinical situations. Coexisting disease states, such as renal or hepatic dysfunction, may require individualized dosing of these agents. The physiologic changes associated with aging may also affect the pharmacokinetic properties of the drugs. If calcium entry blockers are used concurrently with other medications, dosage adjustment or selection of an alternative drug may be needed. Drug interactions between calcium entry blockers and cimetidine, digoxin and quinidine appear to be clinically significant. Individualized dosing in patients who have coexisting disease or who are using other medications is essential to achieve an adequate therapeutic response and avoid adverse effects. Considerations to attain an optimal response in such situations are presented.

(Am J Cardiol 1985;56:105H–111H)

The calcium entry–blocking drugs have been used in the therapy of arterial hypertension for a number of years.[1–3] There are 3 drugs of this class currently available in the United States (Table I) and each has a unique pharmacokinetic profile. Moreover, these drugs differ markedly from some of the currently used antihypertensive agents. The differences both among the calcium entry blockers and between them and conventional therapies are important, because these drugs are playing a role in antihypertensive therapy. An appreciation of the pharmacokinetic characteristics, the dosage modification required in selected disease states and the drug interaction profiles for each of these agents should be useful in achieving optimal therapy in the individual patient.

Pharmacokinetic Parameters

The general pharmacokinetic parameters for the currently available calcium entry blockers are listed in Table I. All 3 drugs are readily absorbed from the conventionally used oral dosage form and attain maximal plasma concentrations within 30 to 180 minutes.[4] They each undergo a significant presystemic elimination (first-pass effect), with verapamil exhibiting a greater presystemic loss (and lower bioavailability) than the other 2 agents.[6–8] Because most of the bioavailability studies performed with these drugs have been done in fasting subjects, there is no information available on the effect of food on this parameter. However, it is possible that the concurrent administration of either a carbohydrate-rich or protein-lipid meal would decrease the extent of first-pass metabolism, as has been demonstrated for propranolol.[9] Therefore, patients are best advised to take these medications either on any empty stomach or before meals to ensure consistency in bioavailability (even though it is possible that a decreased quantity of the active drug moiety reaches the system under these conditions).

All 3 drugs are extensively distributed to most tissues, including the central nervous system. Plasma protein binding of diltiazem and verapamil is independent of concentration over the range of clinically used plasma concentrations;[10,11] thus, no clinically significant drug displacement interactions are anticipated for these agents. Studies with diltiazem have demonstrated a lack of displacement when administered concomitantly with various other compounds—for example, warfarin, propranolol and digoxin.[11] On the other hand, plasma protein binding of nifedipine has been shown to be concentration dependent,[12] but no clinically significant displacement interactions have been reported to date.

The elimination of these agents is primarily handled by hepatic microsomal oxidases with subsequent renal elimination of various metabolites,[4] although 3 to 4% of a dose of verapamil is eliminated in unchanged form. The half-lives of all 3 drugs are similar after a single oral dose. However, the half-life of verapamil has been shown to double after long-term oral dosing [5,13–15]—for example, from 5.7 to 9.6 hours in normal patients[13] and from 6.4 to 12 hours in patients with chronic atrial fibrillation.[15] Thus, in long-term

TABLE I Pharmacokinetic Parameters of Calcium Entry Blockers[4-8]

	Diltiazem	Nifedipine	Verapamil
Oral absorption (%)	>90	>90	>90
Bioavailability (%)	41–67	37–68	10–22
Protein bound (%)	77–80	92–98	83–92
Therapeutic plasma concentration (ng/ml)	40–200	25–100	80–300
Elimination pathway	Hepatic	Hepatic	Hepatic/Renal
Active metabolites	O-desacetyldiltiazem (40 to 45% activity of parent compound)	None	Norverapamil (10% activity of parent compound)
Elimination half-life (hours)	2.1–5.8	1.9–5.8	2.8–6.3*

* Increased with chronic dosage.

TABLE II Effect of Various Physiologic States on Calcium Entry-Blocker Dosage

	Diltiazem	Nifedipine	Verapamil
Pediatric	Not approved—no clinical data available	Not approved—no clinical data available	0.1 mg/kg intravenous (for a maximum total of 3 doses) 240–360 mg/daily, oral
Geriatric	Reduce oral dose by approximately 25% in patients >70 years; titrate slowly, beginning with low dose	No data available, but presumably similar to diltiazem	No data available, but oral or intravenous dose should be reduced by at least 50% for initial dose and titrated slowly
Liver disease	Reduce initial oral dose by 30 to 40% in severe liver disease and titrate slowly with close supervision	No data available, but presumably similar to diltiazem	Initial doses should be 1–3 mg intravenous or 80–120 mg/day oral; monitor closely
Renal disease	No dosage adjustment needed	Pharmacokinetic parameters unchanged, but pharmacologic response significantly enhanced	Avoid use, but if essential, reduce dosage consistent with reduction in creatinine clearance
Diabetes mellitus	Appears to be safe, but should be closely monitored at first	Use caution; conflicting reports in clinical studies	Appears to be safe, but should be closely monitored at first

oral therapy, the dosage interval for verapamil may be extended to 8 or, in some individuals, 12 hours. Similarly, because the shift in half-life and the correlated increase in the area-under-the-plasma-concentration curve occur within the first few days of dosing, dosage escalation should not be undertaken until the patient is assessed at the steady-state plasma concentration; this usually occurs 4 to 5 days after drug initiation. Dose-related changes in the bioavailability of diltiazem have been reported, but the differences are not as pronounced as those of verapamil.[16] It appears that the presystemic elimination of diltiazem is saturable, so that larger doses will result in enhanced bioavailability and subtle increases in half-life.[17] Clinical dosage modification is not required but practitioners should be aware that larger individual oral doses will give a slightly greater response than might be estimated on a strict proportional basis.

The relatively short half-life of the calcium entry blockers might provoke concern regarding the physiologic consequences of abrupt discontinuation. However, studies in patients with unstable angina,[18] variant angina,[19] chronic stable angina[20] and hypertension[21] have shown no withdrawal symptomatology. In contrast, there are 2 reports that describe potential withdrawal symptoms with these drugs. Bala Subramanian et al[22] have described 5 angina patients who developed symptomatology that was suggestive of drug withdrawal upon discontinuation of verapamil and diltiazem. Changes in the ST segment and tachycardia were noted; however, only 2 of the 5 patients actually reported any problem. The inhibitory actions of the calcium entry blockers on sympathetic activity have been proposed as a possible basis for these withdrawal symptoms.[22,23] In a subsequent report, Engelman et al[24] described 4 patients who underwent coronary revascularization surgery after abrupt withdrawal of either nifedipine or diltiazem. Severe coronary vasospasm resulted and was confirmed in 3 of the 4 patients by ST-segment changes in the electrocardiogram. Sublingual nifedipine and intravenous nitroglycerin were effective in ameliorating signs of ischemia in 2 patients; but both of the other patients developed infarcts, and 1 died despite heroic resuscitative measures. It is recommended that patients on long-term calcium entry–blocker therapy be maintained on the medication for 24 to 48 hours postoperatively. If a calcium entry blocker is to be discontinued, a conservative approach would involve decreasing the oral dose by 30 to 35% every 4 to 5 days for a period of 2 weeks, with careful monitoring for any signs of cardiovascular rebound.

Use in Selected Patients

In contrast to certain antihypertensive medications, the calcium entry blockers can be used safely in the majority of patients with concurrent migraine headache,[25] bronchial asthma[26,27] or angina. However, there are a number of clinical situations in which dosage adjustment may be considered (Table II).

Pediatrics: Pediatric use of medications that are conventionally prescribed for adults often calls for significant dosage adjustment. Verapamil has been used in pediatric patients for the treatment of supraventricular tachycardia.[28] Hypotension was noted after "a large dose of the drug," so 0.1 mg/kg was infused intravenously over a 30-second period, with a maximum of 2 additional doses if hypotension did not limit dosing. If extrapolated for body weight, this dosage is equivalent to an individual dose of 7 mg in a 70-kg individual, which is similar to the recommended adult dosage (5 to 10 mg). Oral dosages of 80 to 120 mg, 3 times a day, are also used in children, and this range is also quite close to the adult dosage for the drug. Thus, pediatric use of the intravenous preparation should be based on individual body weight, but oral dosing may be used in the lower range of commonly used adult doses.

Lactation: The authors of the previous study noted that verapamil is useful in the treatment of paroxysmal supraventricular tachycardia in children of all ages, but that it may not be effective in infants under 6 months of age.[28] Nonetheless, the presence of the drug in milk poses 2 potential hazards to the nursing infant —cardiovascular depression and hepatic damage owing to hypersensitivity.[29] The former is presumably related to dose; the latter is not. Andersen[30] reported that the average concentration of verapamil in milk is 23% of the maternal serum level, resulting in a serum level of 2.1 ng/ml in the infant. Although this level of verapamil would not be expected to result in depressed cardiovascular function, hypersensitivity reactions could still occur in the infant. In contrast, Inoue et al[31] noted that the levels of verapamil in the mother's serum and milk were essentially equivalent, raising the projected plasma concentration in the infant to 20 ng/ml. Because the concentration of verapamil in nonionized form is quite high, similar concentrations of verapamil would be expected in maternal serum and milk. Thus, the data of the latter study are more in keeping with calculated projections. Until further studies are done to determine the actual excretion rate of this drug into human milk and the effects of such an exposure on the infant, it is best for women using verapamil to avoid breast feeding. The lack of studies of this type for diltiazem and nifedipine also precludes their use in nursing mothers.

Geriatrics: Because of the apparent microsomal oxidation of these drugs by the liver, the changes in both hepatic drug oxidation[32] and hepatic blood flow[33] noted during the aging process may call for conservative dosing in elderly patients.[34] In a study done with diltiazem in elderly subjects (64 to 75 years), absorption rate appeared to be reduced and half-life was prolonged from 6.6 ± 0.13 hours in 20 to 30-year-old control subjects to 10.9 ± 0.93 in elderly patients.[35] However, there was no change in the bioavailablity of the drug. Although these data are of interest, further studies are needed—particularly because this study evaluated only 3 patients. In general, information regarding the use of calcium entry blockers in the elderly population is lacking. Until more data are available, the tenet, "start low, go slow," should apply to the use of these agents in patients over 70 years of age, considering the potential compromise in hepatic metabolism associated with aging.

Liver disease: All 3 of the currently available calcium entry blockers are extensively metabolized by the liver (Table I). Therefore, liver disease would most certainly have the potential to modify the pharmacokinetic parameters of those agents, with a resultant increase in half-life. Studies with verapamil have demonstrated that clearance may be reduced by approximately 50% and half-life increased to 4 times that of normal controls.[36] Bioavailability was found to be 52.3% compared with 22% in control volunteers. These researchers suggest that cirrhotic patients should receive half of the normal intravenous dose of verapamil or 20% of the normal oral dose in order to avoid untoward effects. Woodcock et al[37] found considerable variation (3.8 to 64%) in the bioavailability of verapamil in subjects with liver disease, and recommend a dosage reduction to 33% of the normal dose. They stress that there is considerable interpatient variation and that some cirrhotic patients may have a "bioavailability actually lower than normal." [38] Subsequent studies in patients with Laennec's cirrhosis have shown decreased plasma protein binding of verapamil in this population in association with a lower concentration of binding proteins. In these patients, higher steady-state levels of verapamil could be anticipated after intravenous, but not oral, administration.[39] Thus, for cirrhotic patients, an intravenous dosage recommendation of 50% of the normal dose is appropriate, as is a recommendation of cautious escalation of oral dose starting from 25% of the normal oral regimen. Because of their significantly higher bioavailability, nifedipine and diltiazem would not be presumed to demonstrate such marked changes in the presence of hepatic disease; however, a cautious approach to dosage increase with these agents is still indicated.

Renal disease: Reports regarding the use of either verapamil or diltiazem in patients with renal disease have identified differential dosing recommendations for these agents. Patients with advanced renal disease who had received either intravenous or oral verapamil showed a significant decrease in apparent volume of distribution, elimination half-life and total body clearance.[40] The renal clearance of verapamil was significantly decreased from 0.38 to 0.004 ml/min/kg after intravenous doses. This was accompanied by a significant decrease in total clearance from 12.08 to 5.33 ml/min/kg. Thus, dosages of verapamil should be lowered significantly in uremic patients as well as in elderly patients in whom renal function may be compromised. In contrast, Pozet et al[41] found that both diltiazem and its main metabolite, desacetyldiltiazem, had similar pharmacokinetic profiles in patients with "severely impaired renal function" and in normal patients. Although this contrast between diltiazem and verapamil may seem difficult to explain, one should consider that 3 to 4% of a dose of verapamil is excreted unchanged,[4] and this may indicate that as much as 30 to 40% of the active drug is absorbed. Diltiazem, on the other hand, has high bioavailability (approximately

50%) and less than 1% is excreted unchanged; approximately 2% of the absorbed dose was found in the urine. Although data are unavailable, nifedipine should have a profile similar to that of diltiazem, but caution should be observed with this drug until studies are performed.

Diabetes mellitus: Verapamil reduces insulin release in vitro in response to both glucose and sulfonylureas.[42] Because of this finding, there may be some concern regarding the use of these agents in the diabetic patient. Rodjmark and Andersson[43] found that both oral and intravenous verapamil actually improved tolerance to orally administered glucose in type II diabetics and had no effect on therapy with glibenclamide. There was also no effect on both glucose tolerance and release in normal individuals. Diltiazem therapy over an 8-day period showed no effect on plasma glucose, insulin or glucagon concentrations.[44] Thus, it would appear that use of diltiazem should also be safe in diabetic patients, although trials have not been done in this specifc population. In contrast, there are equivocal findings regarding nifedipine usage. There are reports of impaired glucose tolerance,[45] reduced insulin secretion and inhibition of glucagon suppression[46] in noninsulin-dependent diabetics; however, other studies have not been able to support these findings.[47] Similarly, in insulin-dependent diabetics, nifedipine administration caused no change in plasma C peptide concentration.[48] Thus, although use of both verapamil and diltiazem seems safe in the diabetic patient, caution should be exercised in the administration of nifedipine until further documentation is available.

Drug Interactions

Calcium entry blockers may interact with other drugs via either pharmacodynamic or pharmacokinetic mechanisms. Pharmacodynamic drug interactions are not discussed here in any detail, because the only ones that have been described in the clinical literature are obvious due to their synergistic nature—for example, the additive cardiodepressant actions of verapamil with disopyramide. Because of the potential atrioventricular nodal depression associated with both diltiazem and verapamil, caution should be used if patients are on therapy with disopyramide, quinidine, procainamide or other antiarrhythmic agents; if possible, these combinations should be avoided. Concomitant use of β blockers has been addressed in another article in this issue;[49] existing data indicate that the combination of calcium entry blockers and β blockers can be tolerated safely in most patients. More caution is required in the use of verapamil and diltiazem, and β-blocker dosage should be decreased to approximately 50% of the baseline dose during combination therapy. It is probably best to avoid the use of the intravenous form of verapamil in patients taking β blockers. If this latter combination is to be used, it is best to discontinue propranolol 24 hours before administering verapamil or to wait 12 to 24 hours after discontinuance of intravenous verapamil to initiate β-blocker therapy. However, if it is deemed clinically essential to use such a combination, the patient should be monitored closely and cardiovascular supportive measures must be readily available.

Several pharmacokinetic drug interactions (Table III) have been reported for calcium entry blockers. Many of these can be ascribed to the extensive hepatic metabolism of these drugs, but their clinical relevance remains to be evaluated. However, when other agents metabolized by the microsomal oxidative system are used concurrently, the practitioner should be aware of potential interactions for either drug.

Cimetidine: Cimetidine, a widely used agent for gastrointestinal disorders, has been shown to reduce hepatic blood flow and inhibit hepatic microsomal oxidative function.[50] When either oral or intravenous verapamil was administered to patients taking cimetidine (1,200 mg/day), oral bioavailability was increased from 26.3 to 49.3%. Despite this pronounced change in bioavailability, which was accompanied by a 39% decrease in clearance, the investigators noted that there was no significant change in PR interval and concluded that "in a patient taking oral verapamil, cimetidine would be unlikely to precipitate atrioventricular nodal conduction block."[51] This finding must be cautiously interpreted, because the investigators used a single-dose methodology in verapamil administration and evaluation. If the drug were given chronically with cimetidine, there would be a chance for greater accumulation because of the increase in half-life associated with long-term dosing.[5,13–15] Thus, patients using these 2 drugs simultaneously should be closely monitored for hypotension, constipation, atrioventricular nodal depression and other dose-related adverse effects. If these reactions occur, the dosage of verapamil should be reduced. In another study, 6 normal subjects were given 40 mg/day of nifedipine for 1 week with 1,000 mg/day of cimetidine, or nifedipine alone in a crossover protocol.[52] An 80% increase in area-under-the-plasma-concentration-time curve and in maximal plasma concentration was reported during concurrent therapy. Plasma clearance of nifedipine was reduced by 40% in the presence of cimetidine. When ranitidine was administered concomitantly with nifedipine, there were no significant effects on the calcium entry–blocker concentration (although a slight increase in plasma nifedipine levels was noted). In an additional study of 7 hypertensive patients, cimetidine administration resulted in a significant exacerbation of the hypotensive adverse effects of nifedipine dosing. Thus, if therapy is needed for concurrent ulcer disease in a patient requiring calcium entry–blocker therapy, it is best to use either ranitidine or sucralfate; neither of these agents has been shown to interact with calcium entry blockers.

Smoking: Cigarette smoking has been shown to stimulate both the heart rate and the activity of hepatic microsomal oxidases. These effects would be antagonistic to the action of any antianginal agent, because increased heart rate increases myocardial oxygen demand, while increased drug metabolism results in lower plasma levels of the drug compared with

those of a nonsmoker. In a study comparing the effects of smoking on the antianginal actions of propranolol, atenolol and nifedipine, it appeared that smoking had the greatest antagonistic effect on nifedipine, because patients showed the greatest improvement after cessation of smoking while taking this agent.[53] However, the interaction appeared to be more of a pharmacodynamic rather than a pharmacokinetic antagonism, because plasma levels of nifedipine did not differ significantly during the smoking and nonsmoking phases of the study.

Digoxin: Although all 3 of the currently available calcium entry blockers have been shown to interact with digoxin, the nature and intensity of the interaction vary from drug to drug. In a study with diltiazem, subjects received a single oral dose of 0.5 mg digoxin in the presence or absence of 1-week pretreatment with 90 mg/day diltiazem. Diltiazem was found to increase the plasma levels of digoxin 3 to 12 hours after digoxin dosing with a concomitant decrease in oral clearance from 3.05 to 2.31 ml/min/kg. There were no significant changes in absorption, peak concentration time, distribution half-life, elimination half-life or apparent volume of distribution.[54] A subsequent study with diltiazem at 180 mg/day indicated that digoxin half-life was prolonged from 36.7 to 44.5 hours during combination therapy.[55] Total digoxin clearance was decreased by 26.9%, although renal clearance did not decrease significantly (16.25% reduction). Digoxin had no effect on the pharmacokinetic parameters of diltiazem. The combined use of diltiazem and digoxin should be avoided in patients being maintained at plasma digoxin concentrations >1.5 ng/ml and in patients with known renal dysfunction. Caution should be used in elderly patients, and therapy with diltiazem in digitalized patients should be initiated with close observation for signs of toxicity.

There are conflicting clinical reports regarding the the interaction of nifedipine with digoxin. An initial report indicated that nifedipine at 30 mg/day for 2 weeks would increase the plasma digoxin level by 45%.[56] However, a subsequent study noted that nifedipine actually increased the extrarenal clearance of digoxin and had no significant effect on renal digoxin clearance, distribution or elimination half-life.[57] This latter study was criticized because of the use of an intravenous challenge with digoxin rather than the conventional oral therapy; however, subsequent studies have demonstrated that concurrent administration of oral nifedipine had no effect on levels of digoxin in either normal subjects[58] or cardiac patients.[59,60] Thus, it would appear safe to use this drug in digitalized patients, but good clinical practice dictates that the initiation of any new medication in the cardiac patient requires careful assessment and monitoring.

In a number of clinical studies, verapamil has been found to have pronounced effects on the pharmacokinetics of digoxin. Klein et al[61] initially reported a 69% mean increase in serum digoxin levels when verapamil (240 mg/day) was administered concurrently. Subsequent studies have shown similar increases in serum digoxin concentration associated with concomitant verapamil dosing in both healthy volunteers[56,62] and patients with chronic atrial fibrillation.[63] In the latter study, in which 49 patients were evaluated, plasma digoxin levels rose from 0.76 to 1.31 ng/ml when concomitant therapy with verapamil (240 mg/day) was used. Doses greater than 240 mg/day had no more significant effect, but the increase in serum digoxin was dose-dependent up to that level. Maximum digoxin concentrations were noted 1 week after initiation of verapamil and returned to baseline 2 weeks after the last dose of the drug. Three mechanisms have been postulated to explain the basis of this drug interaction: decreased renal digoxin clearance,[62] decreased nonrenal digoxin clearance[62] and decreased volume of distribution for digoxin.[63] Further research is needed to assess the contribution of each of these potential mechanisms. The clinical relevance of this interaction is pointed out in the initial studies done by Klein et al,[61] in which 7 of 49 patients receiving combination therapy with verapamil and digoxin had signs of digoxin intoxication. In a more recent report, Zatuchni[64] described 2 patients (73 and 77 years old) with a history of cardiac disease who received either oral or intravenous verapamil while being maintained on digoxin. After 7 days of combination therapy, levels of serum digoxin peaked at 4 ng/ml, and both patients died. If a patient is to be maintained on a combination regimen of this type, digoxin dosage should be reduced by 50%, and frequent serum digoxin measurements should be taken to avoid toxicity.

Quinidine: Although the potential pharmacodynamic interaction between verapamil (and, possibly, diltiazem) and quinidine has been mentioned previously, a pharmacokinetic interaction apparently occurs between nifedipine and quinidine in some patients. Farringer et al[65] reported 2 cases in which con-

TABLE III Pharmacokinetic Drug Interactions with Calcium Entry Blockers

Drug	Calcium Entry Blocker	Recommendations
Cimetidine	Diltiazem, verapamil, nifedipine	Reduce dosage by 50% initially and titrate slowly or use ranitidine or sucralfate
Digoxin	Diltiazem	If digoxin level is >1.5 ng/ml, use with extreme caution and monitor closely; reduce digoxin dose as needed
Digoxin	Nifedipine	Appears to be safe, but monitor closely and reduce digoxin dosage if needed (see text)
Digoxin	Verapamil	Reduce digoxin dosage by 33 to 50% and monitor carefully
Quinidine	Nifedipine	Serum quinidine concentrations may be markedly lowered in the presence of nifedipine; if this occurs, discontinue nifedipine and monitor for rebound increase in serum quinidine

current nifedipine therapy appeared to decrease serum quinidine levels. Discontinuation of nifedipine therapy resulted in an increase in serum quinidine concentration from 2 to 2.5 to 4.6 μg/ml in one case and from 1.7 to 4 μg/ml in the other. Thus, this combination should be used with caution, particularly because of the rebound increase in serum quinidine levels after nifedipine is discontinued. Similarly, if adequate serum concentrations of quinidine cannot be attained, concurrent nifedipine administration should be ruled out as a cause of this problem before larger quinidine doses are ordered.

At present, there is no clinical documentation to support the notion that other drugs may interact with the calcium entry blockers. However, the practitioner should keep in mind the possibility of interactions with such other agents as antidiabetic medications, agents that affect microsomal oxidative metabolism (e.g., disulfiram) and agents that have been shown to inhibit calmodulin (phenothiazine antipsychotic drugs or tricyclic antidepressants are examples of such agents). Each of these agents possesses the mechanistic potential to affect the response to calcium entry blockers.

In summary, there are a number of clinical situations in which the dosage of calcium entry blockers must be modified. Tables II and III summarize them. In most of these situations, it is still possible to achieve an optimal response to the calcium entry blocker if dosage is modified accordingly. However, as in all clinical situations, the practitioner must not only modify dosage, but should also monitor the patient more frequently for potential adverse reactions.

A Symposium: Transdermal Nitroglycerin—Maximizing Therapeutic Efficacy

Introduction

WILLIAM H. FRISHMAN, MD

Nitroglycerin is the oldest pharmacotherapy for the treatment of angina pectoris. In addition to sublingual nitroglycerin, longer-acting preparations are available to provide angina prophylaxis. The most recent formulation of nitroglycerin devised to provide long-acting effect is the transcutaneous sustained-release patch. Since its introduction in 1981, transdermal nitroglycerin has gained wide acceptance in the clinical community. Recently, however, questions have arisen regarding the most efficacious use of transdermal patches. The clinical situations in which patches may best be used and the manner in which they should be administered have emerged as pivotal issues and are now being evaluated. In July 1985, a symposium was held in New York, New York, to discuss the nitrates and to update the available knowledge on the utility of the transcutaneous formulation. This symposium supplement reports on these proceedings.

The symposium Chairman, Dr. Stephen Scheidt, began with an update on transdermal nitroglycerin that included a detailed and critical overview of the clinical trials that have been conducted using transdermal patches. Dr. Scheidt emphasized that differences in protocol design currently make it impossible to reach firm conclusions about the true clinical role of the patches in the long-term management of angina, but noted that there is definitely an indication that the patches are effective in certain clinical situations.

This author then provided an overview of the pharmacology of nitrates, which included their mechanism of action and clinical pharmacology. Dr. Jan Weber followed with a hard look at designs of clinical investigation of antianginal drugs. The difficulties in carrying out an ideal antianginal drug study were highlighted.

Silent myocardial ischemia, a subject currently of great concern and interest, was discussed by Dr. Andrew Selwyn. Dr. William Shell followed with a preliminary study demonstrating the potential utility of transcutaneous nitroglycerin patches for silent ischemia. Dr. John Parker then addressed the problem of

William H. Frishman, MD

nitrate attenuation or "tolerance," specifically analyzing sustained-release nitroglycerin preparations. Dr. John Flaherty proposed alternative dosing strategies for the transcutaneous patches as a potential means of avoiding tolerance.

Now in its second century of clinical use, nitroglycerin is a mainstay of antianginal therapy. Innovative delivery systems have certainly extended the use of nitroglycerin beyond the acute painful attack. We are still attempting to learn definitively how the drug improves angina on the hemodynamic and cellular levels, and how it can be used most beneficially in all of its dosage forms. A unique multicenter trial with nitroglycerin patches is now in progress in conjunction with the Food and Drug Administration, the academic community and industry. This study will hopefully provide us with the necessary information on which to base clinical decision-making for the full range of angina patients. We look forward to the results of this trial so that we can determine the most effective use of the transcutaneous patches for the management of angina pectoris in years to come.

Update on Transdermal Nitroglycerin: An Overview

STEPHEN SCHEIDT, MD

Nitroglycerin (NTG) and its congeners have been used for the therapy of angina pectoris for over 100 years.[1] Sublingual administration provides rapid absorption, immediate therapeutic blood levels and rapid relief of acute anginal attacks, with a total duration of action of 15 to 30 minutes. For more prolonged action, organic nitrate esters, including isosorbide dinitrate, pentaerythrityl tetranitrate and others, were designed to overcome the extensive enterohepatic clearance of NTG. Indeed, such drugs can provide hemodynamic and clinical actions of nitrates for several hours. However, there is wide interindividual variability in absorption and metabolism, and such agents must often be administered 4 to 6 times a day.

Another approach to prolonging nitrate action has been alternative delivery systems for NTG itself. This includes oral time-release capsules that release NTG slowly into the gastrointestinal tract, lozenges that are placed in a buccal pouch and absorbed slowly through the mucous membrane of the cheek as the lozenge dissolves[2] and transdermal NTG delivery. NTG ointment has been available since 1955 but has been used widely following a report by Reichek et al[3] in 1974. Absorption of NTG through the skin or mucous membranes, of course, provides direct venous access, bypassing the gastrointestinal tract and the enterohepatic circulation. However, the ointment produces variable plasma levels, depending on the area of application,[4] and is clinically effective for only 3 to 5 hours.[3] Further, it is sometimes messy and inconvenient to apply.

In late 1981, 3 transdermal NTG delivery systems were marketed: Nitro-Dur® (Key Pharmaceuticals), Nitrodisc® (Searle Pharmaceuticals) and Transderm-Nitro® (Ciba Pharmaceuticals). Transdermal patches release NTG at a constant rate over at least 24 hours. The rate of drug release is determined solely by the area of the patch, following 0-order kinetics. Drug delivery is largely unaffected by skin characteristics, patch location or other physiologic characteristics of the patient, rather than being regulated by the device itself.[5] NTG plasma levels are dose dependent, and steady-state plasma levels are reached within 2 hours and maintained for at least 24 hours.[5] NTG plasma levels achieved with transdermal patches have been reported to range from 0.1 to 0.4 ng/ml for patch sizes between 2.5 and 20 mg/24 hours.[6,7] This may be below the lower limit of the therapeutic range for plasma NTG, which is generally accepted as approximately 1.0 ng/ml.[8] However, the method of measuring NTG plasma levels is controversial. Assays are difficult to perform, improper sample handling may lead to loss of the volatile drug and there is disagreement about the value of measuring venous plasma levels, because the sampling site is downstream from most areas of NTG uptake. Although some investigators have suggested that measurement of arterial NTG levels would be much more valuable, few reports are available.

Although transdermal NTG patches have been widely accepted, their use has stimulated much controversy. Several recent editorials[9,10] have noted the dearth of large well-controlled studies proving efficacy of these systems, and much work must be done before firm conclusions can be drawn. However, a surprisingly large number of studies have been performed, albeit with relatively small numbers of patients; results are summarized in Tables I and II.

One group of trials may be termed "short term"; they generally involve monitoring of clinical and hemodynamic variables for up to 24 hours after application of transdermal NTG. Reichek et al[11] studied low- and high-dose transdermal NTG; the low dose was determined by titration to achieve a decrease in systolic blood pressure of at least 10 mm Hg or an increase in heart beat of at least 10 beats/min, and the high dose was the maximum tolerated by the patient, short of incapacitating headache or other major side effects. The mean low dose was 9.4 mg and the mean high dose 24 mg (Nitrodisc) or 22 mg (Transderm-Nitro). At 4 hours after patch application, bicycle exercise time increased 7% with low-dose transdermal NTG, and 29 and 39% with high-dose Nitrodisc and Transderm-Nitro therapy, respectively, although none of these increases achieved statistical significance. At 24 hours, the effects were small and not statistically significant.

Parker et al[12] studied Nitro-Dur in doses of 5, 10, 15, 30 and 45 mg/hour. At 4 hours after patch application,

TABLE I Short-Term (less than 1 day) Clinical Trials of Transdermal Nitroglycerin for Angina

First Author	Preparation	(Dose) (mg/24 hr)	Other Therapy	Pts. (n)	Exercise Time Increase vs Placebo	
					Early (4 hr)	Late (24 hr)
Reichek[11]	Nitrodisc	9.4 mean[a]	Yes	7	7%	−4%
	Nitrodisc	24 mean[b]		8	29%	5%
	Transderm-Nitro	22 mean[b]		5	39%	0
Parker[12]	Nitro-Dur	5	1/11	11	9%†	6%
		10		11	9%†	4%
		15		11	6%†	−2%
		30		6	35%†	3%
		45		6	31%	6%*
Hollenberg[13]	Nitro-Dur	2.5	?	10	2%	
		5		10	2%	
		10		10	6%	
Naafs[14]	Transderm-Nitro	5	No	10	16%[c]*	
Cerri[15]	Transderm-Nitro	5	No	20	28%[d]*	20%
		10		20	30%[d]*	15%
Pucci[16]	Nitro-Dur	10	2/10	10	63%[d,e]*	45%[e,f]*

* $p < 0.01$; † $p < 0.05$.
[a] Dose titrated to increase heart rate ≥ 10 beats/min or decrease systolic blood pressure ≥ 10 mm Hg.
[b] Maximal tolerated dose short of incapacitating headache or other severe side effects.
[c] Studied at 12 to 16 hours after patch application.
[d] Studied at 3 hours after patch application.
[e] Total work performed.
[f] Studied at 21 hours after patch application.

treadmill exercise duration was significantly prolonged for most doses. However, only the largest dose, 45 mg, prolonged exercise at 24 hours, and this 6% increase, although statistically significant, appears biologically of minor importance.

Hollenberg et al[13] studied 2.5, 5 and 10 mg of Nitro-Dur at 4 and 7 hours after patch application. Although total exercise time changed little, a computerized ST-segment analysis, termed the "treadmill exercise score," was reported to improve by 30% compared with placebo for all transdermal doses studied; 0.6 mg of sublingual NTG showed an even greater improvement in the treadmill exercise score.

Naafs et al[14] reported a 16% prolongation of treadmill exercise compared with placebo, as well as a delay in development of angina during exercise, evaluated 12 to 16 hours after patch application.

Cerri et al[15] found significant improvements of 28 and 30% in exercise time 3 hours after administration of 5 and 10 mg of Transderm-Nitro, respectively, in a nonrandomized crossover study; at 24 hours, improvement in bicycle exercise time was 20 and 15% over placebo for the 5- and 10-mg doses, respectively, but statistical significance was no longer achieved.

Finally, in a nonrandomized, nonblinded study, Pucci et al[16] compared Nitro-Dur, 10 mg/24 hours, to isosorbide dinitrate, 20 mg 3 times a day. Reporting total work performed on a bicycle rather than exercise duration, transdermal NTG produced a 63% increase in total work at 3 hours compared with placebo and a 45% increase at 24 hours, with similar benefit for isosorbide dinitrate.

To summarize, these short-term trials show increase in exercise time compared with placebo at 4 hours after patch administration for both small- and large-dose transdermal NTG. At 24 hours after transdermal NTG administration, benefit is more difficult to show.

Long-Term Studies

In long-term drug trials, a constant dose of transdermal NTG is administered for 1 week or longer, and stress testing is done after administration of the final NTG patch. Parker and Fung[12] found no improvement in exercise time, either at 4 or 24 hours after Nitro-Dur, 15 mg, after 2 weeks of chronic therapy. Hollenberg and Go[13] reported a 25% increase in time to 1 mm of ST-segment depression in 5 patients given Nitro-Dur, 5 mg/day for 4 weeks. Crean et al[17] administered Transderm-Nitro, 5 mg/day to 11 patients for two 2-week crossover periods, and reported a 5% increase in exercise time compared with placebo for the first 2-week period, but a 17% decrease for the third and fourth weeks. Using the maximal tolerated dose of Transderm-Nitro, 10 to 20 mg, they found a 21% increase in total exercise time compared with placebo (difference not significant).

Thompson[18] reported a 30% increase in exercise time at 4 hours and a 25% increase at 26 hours (both $p < 0.01$) after administration of the maximal tolerated dose of Nitrodisc, between 10 and 20 mg, varying according to individual patients.

Martines[19] administered Transderm-Nitro, 5 and 10 mg, for 3 weeks and found a 33% increase in exercise time for the smaller and a 59% increase for the larger dose (both $p < 0.01$), when measured 3 hours after the last transdermal NTG application.

Imhof et al[20] compared Transderm-Nitro, 5 mg, with isosorbide dinitrate, 40 mg 2 times a day, and measured exercise tolerance 3 to 4 hours after the last patch of 2 weeks of therapy. Transdermal NTG significantly prolonged exercise time by 36% compared with baseline measurement ($p < 0.01$); there was also a minor and insignificant improvement compared with isosorbide dinitrate.

Wester and Mouselimis[21] compared Transderm-Nitro, 5 mg, with nifedipine, 20 mg 2 times a day, in an

TABLE II Long-Term Clinical Trials of Transdermal Nitroglycerin (TD-NTG) for Angina

First Author	Preparation	Dose (mg/24 hr)	Duration	Pts. (n)	TD-NTG Exercise Time Increase vs Placebo (P) Early (4 hr)[a]	Late (24 hr)[a]	Anginal Episodes (n/week) P	TD-NTG	Sublingual NTG (tablet/week) P	TD-NTG	Other Results
Parker[12]	Nitro-Dur	15	2 weeks	11	−5%	7%					Sublingual NTG 5 hr after TD-NTG increased exercise time 23% vs TD-NTG
Hollenberg[13]	Nitro-Dur	5	4 weeks	5							25% increased time to 1-mm ST depression

open crossover experiment. After 2 weeks of continuous therapy, duration of bicycle exercise, performed 2 hours after patch application, increased 23% with Transderm-Nitro compared with baseline ($p < 0.01$). Nifedipine showed similar benefit.

Sullivan et al[22] administered Transderm-Nitro, 10 mg, in a study intermediate between "short" and "long term," using a 3-day lead-in period. There was no difference in exercise time 1 hour after transdermal NTG or placebo and a 4.5% decrease in peak exerci time with NTG compared with placebo at 24 hou (difference not significant).

Georgopoulos et al[23] administered Transderm-N tro, 5 mg, for 1 to 2 weeks. Exercise duration was n measured, but ST-segment depression at matche treadmill times was reported to be improved 51% b transdermal NTG at 2, 8 and 24 hours after patc application.

Finally, 4 as yet unpublished trials used Transderm-Nitro in varying doses. Eberhardt* and Yasky* administered Transderm-Nitro, 5 mg and 20 mg, respectively, for 1 week in 12 and 16 patients in double-blind, placebo-controlled, crossover protocols. Twenty-four hours after application of the last patch, Eberhardt found a 25% increase in total work and Yasky demonstrated an 89% increase in total work, both reported as statistically significant. Exercise time was increased by 13 and 68%, respectively, but this parameter was not included in analysis for statistical significance. Andreoli* gave Transderm-Nitro 5 and 10 mg for 3 weeks to 28 patients in a double-blind, crossover trial. Twenty-four hours after application of the last patch, exercise time was prolonged 35% for the 5-mg dosage and 65% for the 10-mg dosage (both $p < 0.01$). Kapoor* administered Transderm-Nitro, 5 mg, for 2 weeks in a double-blind, placebo-controlled, crossover trial in 30 patients. Exercise duration increased 35% 48 hours after application of the last patch ($p < 0.01$).

Thus, results of the long-term trials are mixed, with several published studies showing statistically significant increases in exercise time within 2 to 4 hours after application of the last patch,[18–21] whereas only 1 published study[18] revealed a statistically significant increase in exercise time 24 hours or more after application of the last patch. On the other hand, many trials found improvement in parameters other than the stringent one of total exercise time. Indeed, of the 13 trials listed in Table II, 4 showed statistically significant improvement in exercise time at 2 to 4 hours,[18–21] 2 showed improvement at 24 to 26 hours (Thompson[18] and Andreoli*), 1 showed improvement at 48 hours (Kapoor*) and 2 additional trials reported total work rather than exercise time, and this was significantly improved at 24 hours (Eberhardt and Yasky*). In 1 study exercise times were not reported[23] and in only 4[12,13,17,22] were the results completely negative. Even among these 4 negative trials, one showed 25% increased time to 1 mm of ST-segment depression,[13] and another[17] showed 35% fewer minutes and 7% fewer episodes of ST-segment depression in 96 hours of continuous Holter monitoring, although these did not attain statistical significance.

There are a number of reasons for the inconsistencies in data. Study design varies considerably. Some studies were randomized, some were placebo controlled or crossover, and some, but not all, were double blind. Further, even if study design was blinded, it is unclear how successful the blinding was, because NTG tends to be distinguishable from placebo both to the patient, because of such symptoms as headache, and to physicians, because of decreases in blood pressure or increases in heart rate. Some studies allowed other antianginal therapy and some did not. In several studies it is impossible to determine whether or not other therapy was administered concomitantly. The Methods section of many published studies is not sufficiently detailed to determine the relative severity of coronary artery disease. In most cases, coronary angiograms were not required, and anatomic disease in some groups of study patients may have been considerably more severe than in others.

A cause of considerable concern is the frequent reliance on patients who have participated in previous trials of antianginal drugs. The whole question of "training effects" with repeated exercise testing is not addressed or sufficiently detailed in most published studies.

The number of patients was exceedingly small in all of these trials, averaging 10 in the trials of acute therapy (range 5 to 20) and 14.6 in the trials of chronic therapy (range 5 to 28). In many cases, results were reported that would appear to have clinical significance, yet statistical significance was not achieved. This is perhaps most striking in the oft-cited "negative" studies of Reichek et al,[3] in which 29 and 39% increases in exercise time did not achieve statistical significance, perhaps because only 8 and 5 patients were studied with maximal tolerated doses of Nitrodisc and Transderm-Nitro, respectively.

The final and perhaps most difficult issue to address is the question of what measure of efficacy is clinically most relevant. Because of its widespread availability, possible correlation with prognosis and ease of objective comparison, maximal stress testing is often used, and total exercise time is widely regarded as perhaps the most important measurement of efficacy of any antianginal agent. However, exercise to the point of pain is an unusual situation for the average angina patient in daily life. For most physicians, prevention of anginal episodes or increase in the amount of exercise that can be done short of angina, is the general goal of therapy. Five of the long-term trials summarized in Table II did indeed reveal significant reductions in number of anginal episodes or sublingual NTG consumption, or both, with a median reduction of 63% in anginal episodes and 67% in NTG consumption, although such results are generally discounted as too subjective.

Electrocardiographic ST-segment changes in patients with angina will be discussed under the rubric of "silent ischemia" elsewhere in this symposium. If such electrocardiographic changes do indeed represent ischemia, they may provide objective means of quantifying the antiischemic effect of NTG or any other drug on daily activities short of those producing pain. Unfortunately, the data are too sparse in published transdermal NTG trials to permit even the most tentative of conclusions concerning this therapeutic endpoint.

Given the small number of trials, the differences in study design, the frequent lack of individualized or titrated dosage of transdermal nitroglycerin, the small numbers of patients in most trials, the differences in patient selection and the reliance on only a single objective measurement of efficacy, the exercise stress test, it is not surprising that no clear answer is available concerning the efficacy of transdermal NTG. The final conclusion probably will not be either so enthusiastically favorable as greeted the transdermal NTG patches when first released or so unfavorable as recent

* Personal communication, H. Rosenbach, CIBA Medical Affairs, Summit, New Jersey.

reviews have suggested. Until more research is reported, physicians must recognize that there will be variability in responses of individual patients, as well as in doses of transdermal NTG needed to achieve the optimal response.

Pharmacology of the Nitrates in Angina Pectoris

WILLIAM H. FRISHMAN, MD

Nitrate therapy is the oldest treatment modality for angina pectoris. In addition to sublingual nitroglycerin, longer-acting preparations are available to provide angina prophylaxis. Nitrates work as venodilators and arterial dilators, and by these actions in patients with angina pectoris can reduce myocardial oxygen demands while maintaining or increasing coronary artery flow. On the cellular level, they may increase endothelial prostacyclin release to cause their vasodilating effects. Long-acting nitrates are available in sublingual, chewable, oral, buccal and topical forms. The topical forms include nitroglycerin paste and transcutaneous patches. Long-acting nitrates have a duration of action of 2 to 24 hours, depending on the preparation used. The transcutaneous patches, which provide the longest duration of activity, are being reexamined regarding long-term efficacy and drug tolerance. Nitrates are also available in an intravenous form and in a short-acting sublingual spray soon to be released. The safety of nitrates has been confirmed. Their hemodynamic and safety profiles allow them to be combined with calcium-channel blockers, β-adrenergic blockers or both when trying to improve on the antianginal efficacy of single-drug therapy.

(Am J Cardiol 1985;56:8I–13I)

Organic nitrates are the oldest and most frequently used medications for the urgent treatment of angina pectoris. Nitroglycerin (NTG) was first synthesized by Sobrero in 1846, and he observed that a small quantity of the oily substance placed under the tongue elicited a severe headache. In 1847, Hering developed the sublingual dosage form of NTG, which he advocated for treatment of a number of diseases. In 1857, Brunton administered amyl nitrite, a known vasodepressor, by inhalation and noted that anginal pain was relieved within 30 to 60 seconds. The action of amyl nitrite was transient, however, and the dosage was difficult to adjust. In 1879, Murrell decided that the action of NTG was similar to that of amyl nitrite and used sublingual NTG for the relief of acute anginal attacks and as a prophylactic agent to be taken before exercise. In 1939, Krantz et al[1] reported on their discovery of isosorbide dinitrate. The observations that organic nitrates could be used safely for the rapid and long-term alleviation of angina pectoris led to the widespread acceptance of these compounds.

Chemistry

Organic nitrates are polyol esters of nitric acid, whereas organic nitrites are esters of nitrous acid. Nitrate esters (C-O-NO_3) and nitrite esters (C-O-NO_2) are characterized by a sequence of carbon, oxygen and nitrogen, whereas nitro compounds (which are not vasodilators) possess carbon-nitrogen bonds (C-NO_2). Thus, glyceryl trinitrate (commonly called nitro) is not a nitro compound and is erroneously called nitroglycerin. However, this nomenclature is in widespread use and will be used throughout this review.

Amyl nitrite is a highly volatile liquid that is administered by inhalation. Organic nitrates of low molecular weight, such as NTG, are moderately volatile, oily liquids, whereas high-molecular-weight nitrate esters, such as erythrityl tetranitrate and isosorbide dinitrate (ISDN), are solids. The fully nitrated polyols are partially soluble, and incompletely nitrated compounds are more soluble in water.[2]

Hemodynamic Effects

NTG and organic nitrates are direct dilators of arteries and veins (Table I).[3] The drugs have no direct effects on the myocardium or the cardiac conduction system. Nitrates are taken up directly by blood vessels, which, along with the liver, are involved with metabolic degradation of the drugs.[4]

Nitrates in low plasma concentrations dilate the veins.[5] Maximal venodilation is observed with small to moderate doses of nitrates. Arterial vasodilation becomes more pronounced at higher plasma and tissue nitrate concentrations. With even higher nitrate concentrations, dilation of the systemic and coronary arteriolar circulations occur, with a reduction in both peripheral and coronary vascular resistances.

The magnitude of the vascular response to short-term administration of nitrates parallels the administered dose. However, with long-term administration, the dose-response relation is not seen, probably secondary to nitrate metabolite accumulation.[6] Whether the responsiveness of various regional circulations differ in response to nitrates is not known.

Cellular Mechanisms of Nitrate Action

Nitrates are believed to induce vasodilation by interacting with sulfhydryl groups on nitrate receptors on cell membranes.[7] Nitrates also combine with sulfhydryls within smooth muscles, where they are converted to S-nitrosothiols. These are short-lived compounds that induce an increase in cyclic guanosine monophosphate production, which triggers vasodilation.[8]

Recent studies suggest that the prostaglandins may play a role in NTG-induced vasodilation.[9,10] In open-chest dogs, NTG caused a significant increase in coronary sinus prostaglandin E concentration, which correlated with an increase in heart rate, a decrease in mean arterial blood pressure, an increase in mean coronary artery blood flow and a decrease in mean coronary resistance. After administration of indomethacin (5 mg/kg), trinitroglycerin infusion produced a significantly smaller decrease in coronary vascular resistance and systemic blood pressure and no increase in coronary sinus prostaglandin E concentration.[9] Based on these results, Morcillio et al[9] concluded that the mechanism of action of trinitroglycerin on coronary and systemic resistance may be mediated, at least in part, through the prostaglandin system. Levin et al[10] reported that NTG stimulates synthesis of prostacyclin, a potent coronary and systemic vasodilator, by cultured chick embryo endothelial cells. An increase in NTG concentration produces a dose-related increase in the concentration of 6-keto-$PGF_{1\alpha}$ (Fig. 1).[10] This increase in prostacyclin release from endothelial cells with increasing nitrate doses, and the inhibition of thromboxane (TXB_2) by platelets, further support the concept that prostaglandins may play an important role in the vasodilatation caused by nitrates.

Mechanisms of Angina Relief with Nitrates

It is not exactly known how nitrates relieve angina pectoris.[11] Multiple antiischemic mechanisms may be involved (Fig. 2)[11–13] and the drugs appear to affect favorably both the myocardial oxygen demand and supply.

In the peripheral circulation, nitrates reduce both arterial vascular resistance and venous tone. Accordingly, a reduction in systolic arterial pressure and a decrease in venous pressure, with a resultant decrease in ventricular volume, reduces the ventricular wall tension that is required to generate a given pressure in accordance with the Laplace relation. Taken together with a modest decrease in arterial pressure, these changes result in a reduction in myocardial oxygen demands.[13]

NTG can also increase coronary blood flow and oxygen supply by reducing coronary arterial spasm that may occur at fixed stenotic sites in the coronary vasculature. In addition, dilation of coronary collaterals occurs, whereas autoregulation in the normal vascular bed persists so that a coronary "steal" does not ensue. To the degree by which diastolic ventricular filling pressure is reduced by nitrates, while arterial pressure is not lowered significantly, there is an improvement in the perfusion gradient for coronary flow to occur, which may be very beneficial, especially in the presence of left ventricular failure.[13]

Thus, ischemia is relieved by nitrates from both a decrease in myocardial requirements and an increase in oxygen supply. In any particular patient, any one or all of these hemodynamic benefits may occur, with improvement of the ischemic state. For this reason,

TABLE I Effects of Nitrates

Marked venodilation
Decreased right and left atrial pressures
Decreased stroke volume
Decreased arterial pressure
Reflex tachycardia
Slight arteriolar dilation
Decreased arterial pressure
Increased stroke volume
Dilation of epicardial coronary arteries
Dilation of collaterals

± = questionable additive effects; ↓ = decrease; 0 = no change; ↑ = increase.

nitrates remain a primary treatment for patients with angina pectoris.

The hemodynamic actions of nitrates allow them to be combined with other antianginal drug groups—β-adrenergic blockers and calcium-channel blockers. The hemodynamic effects of these combinations (Tables II and III) may provide increased antianginal efficacy over single drug use.[14,15]

General Principles of Therapy

Sublingual administration of NTG has long-standing universal acceptance as antianginal therapy. Because of its brief duration of action, many attempts have been made to prolong the drug's therapeutic effect by altering molecular configuration or route of administration. Currently available preparations are NTG (sublingual tablet or spray), sustained-release formulations of NTG, NTG ointment and a number of synthetic nitrate esters (ISDN, erythrityl tetranitrate and pentaerythrityl tetranitrate). In addition to the sublingual, topical and oral routes of administration, intravenous, long-acting transdermal and long-acting transmucosal NTG preparations have recently become available. As a result, an era of effective NTG prophylaxis has begun. To provide optimal benefit to patients, clinicians must use NTG more systematically and critically than in the past. Several basic considerations remain central in effective NTG use. When acute relief of established ischemia is the goal, rapid onset of effect is essential, and duration of effect is less important. In contrast, for prevention of angina, predictability and duration of effect are the central issues. Moreover, individual patients may show marked variability in the dose needed to obtain a given effect. Because optimal dosage is unpredictable, careful titration for each patient is needed. A dose producing orthostatic changes in heart rate at rest of 10 beats/min and systolic blood pressure of 10 mm Hg is a practical guide. Such a dose of any nitrate preparation will have antianginal effects, although larger doses may also be tolerated.

Routes of Administration[16,17]

Sublingual: Sublingual NTG avoids first-pass metabolism, so that a transient but effective concentration of drug rapidly appears in the circulation. Relief from acute attacks of angina pectoris begins within 2 to 5 minutes. Its clinical and hemodynamic effects diminish rapidly because of the drug's hepatic breakdown and are usually undetectable by 1 hour. Hence, sublingual administration of NTG (tablet or spray) is most appropriately used for quick relief of acute attacks of angina pectoris. It can also be used for brief periods of anginal prophylaxis in patients with highly predictable angina. When taken immediately before those life-style events likely to provoke an attack, it can prevent onset of symptoms for up to 30 minutes. Otherwise, it is unsuitable for prophylactic use.

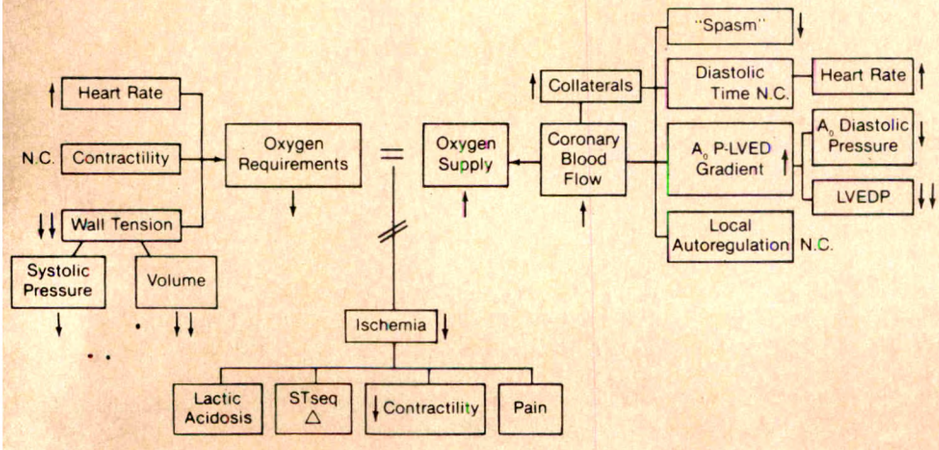

FIGURE 2. Effects of nitrates on the balance between oxygen requirements and supply. Although a reflex increase in heart rate would tend to reduce the time for coronary flow, dilation of collaterals and enhancement of the pressure gradient for flow to occur as the LVEDP falls tends to increase coronary flow. AoP = aortic pressure; LVEDP = left ventricular end-diastolic pressure; NC = no change. Reproduced with permission from Cardiovasc Rev Rep.[13]

Preparations come in tablet, capsule or aerosol form, containing from 0.15 mg to 0.6 mg of NTG (Table IV). If symptoms are not relieved by a single dose, additional doses may be taken at 5-minute intervals, but no more than 3 tablets should be used within a 15-minute period. Because NTG gradually loses potency in the tablet form through volatilization, it is packaged in glass containers with tightly fitting metal screw caps. Tablets should be kept in the original container with the lid tightly closed after each use, and the compound should not be exposed to heat. Physicians should take ample time to explain to patients how to use NTG correctly, because studies indicate that many patients fail to obtain maximal benefit from it, especially as a short-term prophylactic agent.

Sublingual and chewable preparations of ISDN and NTG congeners have been developed to prolong nitrate effectiveness by reducing hepatic deactivation. Unfortunately, they also have a weaker effect on vascular smooth muscle. As a result, these molecular alterations have no inherent superior benefit, because much higher doses are needed to obtain equipotent effects (Table IV). Doses as high as 30 mg have been frequently administered. Onset of action is from 3 to 15 minutes, and effect may last for as long as 2 hours. The prolonged effect would probably not exceed equipotent doses of sublingual NTG. The Food and Drug Administration classifies these drugs as "probably" effective for the treatment of acute anginal attacks and for prophylaxis in those situations likely to evoke such attacks.

Oral administration: Despite controversy regarding their beneficial effect, oral NTG and nitrate esters have found widespread use in the therapy of angina pectoris. Because of extensive first-pass metabolism, large doses (e.g., 30 mg of ISDN 4 times a day) are needed to overwhelm hepatic enzymatic breakdown so that substantial amounts of the active form can reach the systemic circulation. Relative to the other nitrates at equipotent doses, onset of effect is approximately 30 minutes and duration of action only 3 hours after oral ISDN. With larger doses, a longer duration of action is achieved. For all oral preparations, doses often greater than those recommended by manufacturers may be necessary to produce the desired therapeutic effect. Such large doses are likely to cause significant orthostatic effects and severe headaches. With long-term administration, there are signs of partial tolerance; duration and magnitude of effect have been shown to diminish.[18,19] Sustained-release oral preparations are now available and appear to have a longer duration of action (Table IV).

Topical administration: NTG ointment or paste was developed more than 25 years ago, but not until 1974 were its sustained therapeutic effects for up to 3 to 4 hours accepted.[20] Usually a 2% NTG ointment is applied to the skin in 1- to 3-inch doses (15 mg/inch) and then spread in a uniform layer. Because skin permeability increases with increased hydration, covering the applied area with plastic and taping the edges will increase water content of the skin and enhance absorption. It will also prevent the medication from ending up on the patient's gown or clothing. Studies reveal that anterior chest wall or upper limb application derives optimal clinical benefits while keeping headaches to a relative minimum. Absorption may be variable, and the delay in onset of action is approximately 30 minutes.

TABLE IV Dosage and Kinetics of Nitroglycerin and Long-Acting Nitrates

Medication	Usual Dosage	Onset of Action	Duration of Action
Sublingual NTG	0.3–0.6 mg	2–5 min	10–30 min
Aerosol NTG	0.4 mg	2–5 min	10–30 min
Sublingual and chewable ISDN	2.5–10 mg	3–15 min	1–2 h
Sublingual and chewable ET	5–15 mg, 10 mg	3–15 min	2 h
Transmucosal NTG	1–3 mg	2–5 min	3–5 h*
Oral NTG (SR)	2.5–9 mg	30–45 min	2–8 h*
Oral ISDN	5–30 mg	15–30 min	3–6 h
Oral ISDN (SR)	40 mg	30–60 min	6–10 h
Oral ET	10 mg	30 min	Variable
Oral PET	10–40 mg	30 min	3–6 h
Oral PET (SR)	30–80 mg	Slow	6–10 h
Oral ointment (2%)	½–2 inches	20–60 min	3–8 h
Transdermal NTG	5–10 mg	30–60 min	Up to 24 h
Intravenous NTG	5–300 μg/min	Immediate	Transient

* Duration of action lengthens with increasing dosage.
Adapted with permission from Am J Med.[16]
ET = erythrityl tetranitrate; ISDN = isosorbide dinitrate; NTG = nitroglycerin; PET = pentaerythrityl tetranitrate; SR = sustained release.

Cutaneous administration of NTG permits gradual absorption, yielding a truly long-acting effect. Topical application is recommended for the prevention and treatment of anginal attacks, especially at night. The optimal dosage is determined by starting with a half inch of ointment and increasing by half an inch every 3 to 4 hours until headache occurs, then decreasing to the largest dose that does not cause headache. Sites of application should be rotated to avoid skin irritation.[21] Although long-term administration does not clinically appear to lead to tolerance, gradual reduction in dosage and frequency of application over a 4- to 6-week period is advised to prevent withdrawal symptoms during termination of treatment.[20,21]

Recently, 3 slow-release transdermal NTG preparations have been marketed, with the hope of providing a simple once-a-day method for constant antianginal prophylaxis. The preparations contain NTG and a reservoir material and are designed to continuously release NTG into the circulation over 24 hours after a single application. Unfortunately, despite tremendous patient satisfaction with these patches, the clinical data available to date have not shown the long-term clinical efficacy envisioned.[22–24] The relatively small doses used provide 24-hour blood levels equivalent to the levels obtained using half an inch of NTG paste applied every 8 hours. These low reference levels may not provide effective antianginal prophylaxis regardless of route of administration. Additionally, data predicting therapeutic effect from blood levels is lacking for all long-acting nitrates. Until convincing data are available, it may be unwise for physicians to rely solely on any one of these preparations on a once-a-day basis

in patients with rest pain, coronary spasm or in those who are severely limited. Despite these drawbacks, data should be forthcoming from studies using larger doses, indicating that these products will fulfill their promise to provide continuous, long-term antianginal prophylaxis.

Buccal nitroglycerin: Pharmaceutical manufacturers continue to demonstrate considerable creativity in devising new formulations of NTG. The latest release is long-acting transmucosal NTG.[25,26] This product contains NTG in an inert polymer base that releases the NTG over a sustained period. As with sublingual NTG, onset of action is almost immediate, and as with long-acting transdermal preparations, nitrate release is gradual and uniform, lasting for as long as 5 hours. Hence, patients can use buccal NTG for relief of an acute angina attack as well as for long-term prophylaxis.

The tablet may be inserted under the upper lip, between the buccal mucosa and gingiva or in the buccal pouch. Patients can eat, drink and talk while the tablet is present. Another attractive feature is the close correlation between therapeutic effectiveness and physical presence of the tablet in the mouth. As with sublingual NTG, a suitable starting dose may be determined by checking for orthostatic changes at 3 minutes after administration. If angina persists or recurs, it need only be determined whether the attack occurred when the tablet was present or already dissolved. If present, a larger dose may be used. If dissolved, administration should be more frequent. Hence, with the combination of all of these practical features in the buccal form, a single nitrate may be substituted for the multiple drug regimens now commonly used.

Intravenous nitroglycerin: An NTG formulation for intravenous administration is available in the United States. Infusions may be used, with dilutions of 25 to 400 μg/ml; the concentration is based on the patient's fluid requirements. Initial dosage should be 5 μg/min, with increases of 4 μg/min every 3 to 5 minutes until a drop in blood pressure or a decrease in pain is noted. If no response is seen with a dose of 20 μg/min, increments of 10 and, later, 20 μg/min may be used.

There is no fixed optimal dose. Because of variations in the responsiveness of individual patients, each patient must be titrated to his or her desired level of hemodynamic function. Because NTG adsorbs onto plastic, special tubings have been synthesized to overcome this problem. Intravenous NTG is indicated in acutely ill patients who are hospitalized and when another route of administration is not feasible. It is also efficacious in such conditions as complicated myocardial infarction,[27] unstable angina, coronary vasospasm, pulmonary edema and hypertension, and during coronary bypass or neurosurgical procedures. At high concentrations, intravenous NTG is a potent arterial as well as venous dilator.

Noncardiac Effects

Because smooth muscle is generally dilated, gastrointestinal motility, esophageal spasm and biliary tree spasm are decreased. The genitourinary system may be similarly affected. The relief of angina pectoris and esophageal spasm may not be differentiated. Studies indicate that pulmonary vasculature dilates, pulmonary artery pressure decreases and there is mild bronchodilation.[2]

Absorption, Metabolism and Excretion

The biotransformation of organic nitrates is the result of reductive hydrolysis catalyzed by the hepatic enzyme glutathione organic nitrate reductase. The enzyme converts the lipid-soluble organic nitrate esters into more water-soluble denitrated metabolites and inorganic nitrite. The partially and fully denitrated metabolites are considerably less potent vasodilators than are the parent compounds. The liver has the enormous capacity to catalyze this reaction. The biotransformation of organic nitrates is a major factor determining their duration of action and the relative efficacy of the drugs given by different routes of administration.[2]

Tolerance and Dependence

A major concern of long-term nitrate therapy is whether tolerance develops to these drugs. Nitrate tolerance was first documented in animal in vitro studies by Needleman et al[28] on vascular strips. These studies found a tolerance effect that was related to nitrates reacting with reduced sulfhydryl groups on a cell membrane, leading to the formation of disulfide linkages and the release of inorganic nitrite (denitrated metabolites). This reaction is believed to convert the "nitrate receptor" to the disulfide form, which has a lower affinity for the nitrates. In humans, the fact that the vascular headaches occurring after nitrate administration often disappear with continued use of the drugs suggests that some form of tolerance is occurring. Indeed, several investigators have reported tolerance to nitrates in humans.

Despite many published warnings about nitrate tolerance,[29–32] little evidence is available to suggest that it is a common clinical problem. However, some data do indicate decreased antianginal effectiveness with long-term use of large doses administered orally.[29–32] Studies of exercise-induced angina confirm some attenuation of the effects of nitrates on heart rate and systolic blood pressure after long-term therapy.[30] Overall, however, the antianginal benefit provided by long-acting nitrates appears to be persistent, and the efficacy of NTG for the management of an acute anginal attack remains unimpaired.

Because large-dose usage is increasing and there are newer preparations aimed at long-term prophylaxis, clinicians must be cautious of the possible development of withdrawal symptoms. The industrial medical literature is replete with descriptions of withdrawal symptoms, including severe headaches, chest pain, acute myocardial infarction and even sudden death in workers chronically exposed to nitrate powder and vapor.

Until more information is available regarding the long-term effects of large doses of nitrates, the clini-

cian should be cautious regarding continuous nitrate prophylaxis, especially in patients with only mild angina pectoris. Most important, patients should be cautioned not to discontinue nitrate medications abruptly.

Side Effects

In general, nitrates are well tolerated. Headaches and postural dizziness are the most frequent side effects, and are often noted early during treatment. The headaches usually disappear after several days to 2 weeks and may be controlled by temporary reduction in dosage. In some patients, generalized vasodilation may cause profound hypotension. The hypotension and resultant reflex tachycardia can reduce coronary perfusion pressure and worsen anginal symptoms. As a result, all patients should be instructed to be in the supine position when taking an NTG preparation until susceptibility to orthostatic hypertension is determined.

Nitrates sometimes cause mild nausea. Patients with glaucoma can safely use NTG.

Contraindications

Hypersensitivity or an idiosyncratic reaction to nitrates contraindicate their use. Because these drugs may increase intracranial pressure, they should be used with great caution in patients with head trauma, cerebral hemorrhage or postural hypotension. Angina pectoris owing to valvular aortic stenosis or obstructive cardiomyopathy should not be treated with nitrates, as the decrease in preload may seriously decrease cardiac output or precipitate pulmonary edema.

Problems Associated with Clinical Evaluation of Antianginal Medications

JAN R. WEBER, MD

Assessing the efficacy of antianginal medications is not as easy as it might first appear. Many factors, including the protocol, the subjects chosen for study and the physicians conducting the trial, may produce study bias and thereby yield equivocal results. Objectively attempting to quantitate a subjective event such as angina inherently poses many difficulties. The variable nature of anginal episodes makes identification of attacks, or conversely, elimination of such attacks, difficult to assess.

In terms of the protocol, it is necessary to determine what indexes will be used as criteria of efficacy, what doses, either standard or maximally tolerated, will be used for study and what measures will be taken to nullify placebo effect. In terms of patient selection, the varying methods of confirming the diagnosis of ischemia and the questions of concurrent illness, compliance and life-style alterations are all factors that can make findings difficult to elucidate. Finally, investigator bias may be introduced into study results because of prestudy prejudice, involvement in data acquisition and interpretation of findings. It is unlikely that any investigator or group of investigators will ever produce a protocol applicable to all types of antianginal medications that will be universally convincing. Conclusions regarding the efficacy of any antianginal medication will undoubtedly continue to be predicated on assessments made by independent investigators using a variety of research protocols, none of which is likely to be perfect.

(Am J Cardiol 1985;56:14I–18I)

The typical angina episode, vividly described by Heberden[1] and Osler,[2] respectively, as a "choking" or "strangling" sensation associated with the feeling of "impending doom," would seem unlikely to pass without notice. To determine the clinical efficacy of an antianginal agent, it should then be a simple matter of having subjects who have angina record the number of attacks during a specific time interval and then determine whether the number of attacks is significantly reduced during a similar interval in which they are being treated with an antianginal agent. Unfortunately, this task is nowhere near as easy as it first appears, and numerous investigators have expended enormous amounts of time, energy and resources to determine whether new "antianginal" formulations are truly effective.

The Protocol: What Shall We Measure?

Not all anginal episodes are as distinct as those described by Heberden and Osler. In reality, angina is a subjective sensation of discomfort that is characterized somewhat differently by each patient experiencing it.[3] While the classic presentation of substernal chest pressure afflicts a significant number of patients, others may experience coronary ischemic symptoms such as pain or discomfort in the neck, jaw, shoulder, arm or back. It may also take the form of indigestion, heartburn, nausea or breathlessness.[4] Thus, any ailment that produces any of these types of symptoms can easily be confused with angina, and episodes counted as angina may have little or nothing to do with coronary circulatory problems. Conversely, episodes of true coronary ischemia may easily be overlooked by the patient who misconstrues anginal discomfort, ascribing it to an unrelated malady.

Even in patients with well-defined anginal patterns, degrees of severity are found that range from extremely mild to extremely severe, and in counting attacks, it is not clear whether an attack of mild severity should count to the same degree as an extreme one. Patients often learn to attenuate or terminate the activity that appears to be producing angina, and thus, minor alterations in activity patterns may significantly affect reports of anginal frequency.

The number of anginal attacks can also be altered through the use of prophylactic sublingual nitroglycerin (NTG). When a person is about to perform an

From the Department of Cardiology, Hahnemann University, Philadelphia, Pennsylvania.

Address for reprints: Jan R. Weber, MD, Department of Cardiology, Hahnemann University, Philadelphia, Pennsylvania 19102.

activity known to produce angina, it is an appropriate and accepted practice to self-administer NTG sublingually in anticipation of increased cardiac work. By this method, angina may to a large degree be prevented. Should the patient be given a long-acting agent that raises the anginal threshold, the prophylactic use of sublingual NTG may be voluntarily reduced, but the difference between treatment and pretreatment anginal attack frequency would be obscured in spite of the effectiveness of the test medication. Thus, it becomes essential in long-term studies to consider the number of prophylactic sublingual NTG in tablets taken by the subjects.

Recent studies using sensitive Holter monitoring techniques have confirmed the presence of intermittent asymptomatic myocardial ischemia.[5,6] It has been demonstrated that patients with overt angina are frequently unaware of many ischemic events that occur throughout the day. Additionally, many who are afflicted with coronary occlusive disease have no awareness of the presence of myocardial ischemia even though electrocardiographic changes that suggest cardiac muscle jeopardy occur frequently. Thus, in considering the efficacy of an antianginal medication, it may be appropriate to monitor ST-segment changes on the electrocardiogram around the clock to include episodes of silent ischemia as well as overt ischemia in the counting of ischemic episodes experienced.

Attempts to avoid the problems that result from the subjective nature of anginal symptoms by measuring serum levels of an agent under investigation have also met with difficulty. Such studies begin with the assumption that a particular substance is effective in the treatment of angina and then attempt to determine whether the agent in question provides "therapeutic" levels of the substance in the serum of the subject being treated. If such levels are achieved, the substance is considered effective; if not, it is considered ineffective. In addition to the difficulties associated with accurately assessing levels of medications that appear in nanogram or picogram quantities,[7] the basic premise—that "therapeutic level equals therapeutic effect"—may not be correct. Gradual attenuation of certain effects (tolerance) has been clearly demonstrated with many pharmacologic agents, such as prazosin and β blockers, and may also be present in nitrates and perhaps in calcium-channel blockers. Thus, the level of medication capable of producing hemodynamic changes at one time may be insufficient to produce similar hemodynamic changes at a later date.[8]

Inability to measure blood levels of antianginal medications accurately led to major damage to the credibility of the pharmaceutical industry as a result of studies reported in the early 1970s. In spite of the widespread use and acceptance of long-acting oral nitrates at that time, inadequacies in experiments with rat livers led to the erroneous but widely publicized conclusion that "orally administered organic nitrates are absorbed in the portal circulation and are rapidly and completely degraded by liver enzymes before reaching the systemic circulation and therefore can have little chance of producing vasodilation."[9] Such reports led W. S. Aronow and others to conclude that "long-acting nitrates are ineffective as antianginal agents."[9–11] As a result, there was a significant reduction in the use of long-acting oral nitrates until subsequent work confirmed the presence not only of active agent in posthepatic blood but also of biologically active metabolites.[12] Additional clinical investigation by Aronow[13] led to the conclusion that the data accumulated from the initial rat studies "no longer appear relevant to considerations regarding patients." On the positive side of this controversy, it must be said that the initial skepticism did in fact lead to additional investigation, which further clarified the physiology, pharmacology and dose-response relations of orally administered nitrates.

The difficulties encountered with assessing changes in frequency of angina, use of sublingual nitroglycerin and serum levels have led the Food and Drug Administration to develop criteria for assessing the efficacy of antianginal agents based primarily on symptom-limited treadmill exercise testing.[14] This method assumes that a patient's anginal threshold can be accurately and reproducibly quantitated and that an agent's effectiveness can be determined by comparing pretreatment performance with performance during therapy.

Unfortunately, the significant day-to-day variation in a subject's treadmill performance[15] and the circadian changes in exercise capacity make this method less than ideal.[16] There is, in addition, a "training" effect associated with repetitive exercise testing, related not to actual physical conditioning but rather to learning the treadmill walking technique.[17] These fluctuations in exercise performance led to the acceptance of a ±15% variation in treadmill time as a tolerable baseline value for determining pretreatment capacity. This variation, however, might completely obscure a positive response to active agent in studies not using enough qualified patients.

Subject fatigue, an additional problem associated with exercise testing that has been encountered in the evaluation of the long-acting transdermal NTG preparations, may be important. Because these patches are thought to be effective for 24 hours or more, many studies designed to assess them require patients with presumed ischemic heart disease—relatively deconditioned subjects—to exercise to the point of maximal tolerable angina as many as 5 times in the same day.[18] This can average as much as 35 minutes of exercise for patients who are generally accustomed to only limited activity. These same patients are then asked to return early the next morning for yet another exercise test to determine if the patch has maintained efficacy 24 hours after application. The role of muscle fatigue and musculoskeletal pain in limiting a subject's performance at that time needs to be evaluated before results of such studies can be convincing.

Secondly, and more fundamentally, it is not clear whether maximal exercise testing is appropriate for the evaluation of these long-acting preparations, because the 2 most important determinants of treadmill performance, heart rate and blood pressure, are not significantly affected by nitrates at high levels of exer-

cise.[19] Thus, the coronary vasodilatory component of nitrate activity and its role in prevention of coronary vasospasm at lower levels of activity are overlooked by studies predicated solely on exercise performance.[20–22]

Nullifying the Placebo Effect

A major consideration in the design of any clinical research is the placebo effect. It is well established that significant untoward reactions, as well as major improvement in symptoms, can be produced by the administration of placebo. Failure to consider the extent to which adverse effects occur as a result of a placebo may result in the underestimation of the utility of a medication. At the same time, failure to consider a placebo's positive effects may also lead to overestimation of positive response, since many individuals indicate subjective improvement in symptoms and actually perform better in objective tests after administration of an inert substance. Because angina is a subjective sensation, it is not surprising that the effect of placebo on persons with angina may be quite profound. Thus, it is necessary to begin with a research design that includes accurate determination of a clinical baseline value and then compares the response of a group of subjects receiving placebo with their response to active agent. Additional credibility is gained by then proceeding to a washout phase followed by crossover to allow for group comparisons as well as individual comparisons.

Establishment of accurate baseline values is made difficult for a number of reasons. Accurate record-keeping by the study participants is difficult and often unreliable. Climatic variations, which occur during a prolonged study, may be significant, because subjects with a component of coronary vasospasm may develop more attacks during the cold winter months than during the warm months. In addition, patients or their physicians may alter other antianginal medications during the study, a factor that affects not only the baseline but also affects subsequent portions of the research.

Several recent works indicate that various combinations of antianginal medications may be more effective than others.[23,24] It has been suggested that the combination of nitrates with β blockers may be more effective in the treatment of angina than the combination of nitrates with calcium-channel blockers. In addition, the use of members of all 3 categories of antianginal agents (nitrates, β blockers and calcium-channel blockers) may, in many persons, be less effective than the use of any 2 of these agents.[25] Thus, it may be inappropriate to test the efficacy of antianginal medications without discontinuing all other long-acting antianginal agents during the test. Some of the recent work assessing efficacy of the transdermal NTG preparations studied patients in whom nitrates were added to calcium-channel blockers or β blockers in an uncontrolled fashion.[26] Thus, data from these studies must be discounted, owing to the unpredictability and variability of interaction between these groups of medications.

There are also problems with keeping clinical trials "blind" throughout their course, particularly when the agent being tested is obviously effective. When the patients become aware of the salutary effect of the medication, their reports of efficacy and adverse effects can no longer be considered unbiased. Conversely, when uncomfortable adverse effects develop, patient responses to objective testing may be significantly attenuated. In testing transdermal NTG preparations, in which the delivery system is visible to the patient, subjective response to the esthetics of the patch may also play a role in subjective as well as objective response.[27] It is also difficult to produce a double-blind study when investigators are allowed to measure physiologic parameters such as blood pressure and heart rate. In many cases, comparison with baseline data easily allows for the identification of patients receiving active agent. This knowledge may prevent the unbiased acquisition of objective and subjective data.

The Patient: Whom Shall We Test?

Identification of patients with chronic stable angina pectoris produced by coronary occlusive disease who have no contraindications to participation in research protocol and who are willing to do so is a difficult and time-consuming task. On the basis of history alone, the diagnosis of coronary occlusive disease may be made with a reasonable degree of accuracy. This degree of accuracy, however, may not be sufficient to provide meaningful data in the study of antianginal medications, where placebo effects may be profound and the differences between treatment group and placebo group may be small. It is therefore necessary to confirm the diagnosis using one of several criteria. A positive exercise test based on changes in the ST segment of the electrocardiogram is of little help, because this finding may be present in patients with normal coronary anatomy. Exercise radionuclide studies improve predictive accuracy significantly, but once again, false-positive results are not infrequently reported.[28] A history of myocardial infarction has also been suggested as a criterion for inclusion in antianginal medication assessment. Unfortunately, in many cases, infarction is produced by the presence of isolated single-vessel coronary artery disease, and once infarction has occurred, the remaining coronary circulation may be entirely normal. Subsequent chest discomfort in such a person may have nothing to do with coronary occlusive disease.

Cardiac catheterization has long been considered the "gold standard" for assessment of coronary anatomy, with $\geq$60% narrowing considered sufficiently severe to produce symptoms of effort-induced coronary ischemia. However, assessment of coronary angiograms is subject to observer error, which may under- or overestimate the significance of a coronary artery narrowing when compared with autopsy specimens and does not definitely confirm a cause-and-effect relation between lesion and symptoms.[29] Presence or absence of collateral vessels, thickness of the myocardium,

pressures within the ventricle and concomitant valvular disease may also play roles in determining the "significance" of a coronary artery narrowing. Also, the presence or absence of coronary artery vasospasm further clouds this picture.

Coronary artery disease often occurs in the presence of other cardiac ailments that are capable of producing angina-like pain. In a patient in whom mitral valve prolapse, hypertrophic cardiomyopathy or pericardial disease is also present, symptoms attributed to coronary ischemia may indeed be the result of one of these other abnormalities. Additionally, diseases of the gastrointestinal, pulmonary, musculoskeletal and nervous systems may also produce symptoms that mimic or mask angina pectoris.

Thus, to confirm the presence of angina produced by coronary occlusive disease, it becomes necessary to confirm that symptoms truly result from an oxygen supply-and-demand imbalance caused by significant coronary occlusion. Catheterization, exercise testing using radionuclides and clinical evaluation to exclude the presence of other ailments capable of producing angina-like symptoms may be necessary to produce a pure cohort of patients for study.

Problems with Compliance

In long-term studies, it becomes difficult to confirm whether a patient has been taking the medications regularly and according to the specifications of the protocol. Patients are highly prone to skipping doses of the medication or taking the medication at incorrect time intervals. One is forced to rely on the integrity of the individual patient for accurate record-keeping in most cases. It is also important to keep accurate records of other antianginal medications prescribed for the patient. Should the study medication produce significant reduction in angina, patients may be tempted to reduce their intake of other antianginal agents, thereby producing data that underestimate the efficacy of the agent being tested. This further emphasizes the need for eliminating other antianginal medication from treatment regimens as a part of the study design.

Intake of nonmedicinal substances may also alter anginal patterns or disrupt the absorption or metabolism of the study agent. The time of ingestion of the study drug relative to meals may significantly affect absorption in some patients, and alcohol consumption may alter metabolism of substances that are degraded by the liver. Life-style alterations may also affect reported antianginal efficacy. When patients become aware of a drug's salutary effects, they may increase their level of activity in response to their increased "cardiac reserve." Thus, if a patient originally experienced angina after climbing 1 flight of stairs, he may now be able to climb 2 flights of stairs before experiencing angina. In both instances, the number of anginal attacks recorded will be equal, even though the study medications significantly improve functional capacity. Climatic changes may become significant in studies that extend beyond seasonal changes and result in variations in patient exposure to cold.

The Physician: Who Shall Test?

Through the design of the research protocol, an investigator's pretest bias or prejudice can be neutralized. Unfortunately, as discussed, it may be difficult to produce totally blind studies because of the perceptions of both the participants and the observers. In an era in which many research activities are sponsored by pharmaceutical companies that have spent millions of dollars developing a new medication, the desire of the investigator to show efficacy may significantly, albeit subtly, influence the outcome of the study. It is nevertheless imperative for the principal investigator to personally monitor quality control in the acquisition of data to assure consistency in the recording of both subjective and objective information. Accuracy is more likely to be obtained when the same observer is used throughout the entire study.

The greatest opportunity for prestudy bias or prejudice to occur is after the study is completed and the data interpretation begins. Inappropriate statistical manipulation, arbitrary exclusion of data that may be relevant but appears to be inconsistent with the mean and the drawing of broad conclusions based on a narrow range of data are errors that must be constantly avoided.

Conclusions

In summary, the ideal protocol, the ideal patient and the ideal investigator have not been found. In the assessment of antianginal medication, the subjective nature of this ailment, wide variability in the severity of coronary occlusive disease, poorly defined interactions with other agents and pretest study bias all contribute to the difficulty in determining effectiveness. It is unlikely that any investigator or group of investigators will ever produce a protocol applicable to all types of antianginal medications that will be universally convincing. Conclusions regarding the efficacy of any antianginal medication will undoubtedly continue to be predicated on assessments made by multiple independent investigators using a variety of research protocols, none of which is likely to be perfect.

Activity of Transient Myocardial Ischemia Out of Hospital in Coronary Artery Disease and Implications for Management

MICHAEL B. ROCCO, MD, STEPHEN CAMPBELL, MB, JOAN BARRY, BA, GEORGE REBECCA, MD, ELIZABETH NABEL, MD, JOHN DEANFIELD, MD, and ANDREW P. SELWYN, MD

The management of patients with angina pectoris is based largely on the severity of symptoms, coronary anatomy and left ventricular function. The outcome for these patients is highly variable and depends largely on the degree of ischemic damage to the left ventricular myocardium. Recent work suggests that exercise-induced myocardial ischemia with or without angina is associated with a poor prognosis. Ambulatory monitoring of the electrocardiogram has revealed that most patients have frequent and prolonged episodes of transient ischemia out of hospital. These episodes are often asymptomatic and associated with ordinary everyday activities. In addition, ambulatory monitoring has demonstrated that transient ischemia during daily life has a circadian variation with exacerbations and peak density of ischemia in the first 4 to 6 waking hours of the day. Further studies have demonstrated that regional decreases in coronary blood flow occur during these ischemic episodes and have the same features seen out of hospital on continuous monitoring.

These newly noted characteristics of transient ischemia raise a number of practical questions for treatment. Is it necessary to relieve all ischemic activity quite apart from that which occurs with chest pain? Does present use of antianginal medication neglect the early morning increases in transient ischemia that occur, and are different dosage regimens required to treat ischemia adequately? Does suppression of all ischemic activity further protect myocardium and improve prognosis for the patient?

(Am J Cardiol 1985;56:19I–22I)

The management of patients with angina pectoris and other manifestations of coronary artery disease (CAD) is lifelong and medical. Although surgery and angioplasty may be required in some patients, they do not replace the need for vigilance in the control of symptoms, risk factor modification, identification of high-risk groups for infarction or sudden death and continued strategies to prevent ischemic myocardial damage. The association of angina with ST-segment changes on the electrocardiogram (ECG) and increases in heart rate and blood pressure has led to the wide-scale use of exercise-induced ST-segment depression in the diagnosis, prognosis and therapeutic management of CAD. Although relief of symptoms and improvement in exercise performance are thought to be necessary to show treatment efficacy, clinicians have realized for years that angina pectoris is subjective, characterized by exacerbations and remissions in activity, known to occur at changing thresholds in different circumstances and mimicked by many other conditions.

There is now a growing realization that episodes of transient regional myocardial ischemia occur without symptoms and are not associated with exercise or increases in heart rate. Therefore, relief of symptoms and improved exercise tolerance in themselves may not prevent ischemic insult to the myocardium. The purpose of this article is to discuss some newly noted clinical features of ischemic heart disease as they apply to out-of-hospital patients engaged in their usual daily activities. These characteristics of disease activity may not be apparent from conventional testing and assessment of symptoms. They can be quantified objectively in individual patients and may represent features of the disease that require close surveillance and control in order to achieve the goals of prevention of myocardial damage and improved prognosis.

Prognosis

Long-term clinical trials have shown that disturbances of left ventricular function (as manifested by decreased ejection fraction or symptoms of congestive heart failure), ventricular ectopic activity and angiographic extent of CAD (particularly left-main stenosis) are determinants of prognosis in patients with CAD.[1,2] Apart from the anatomic considerations of the extent of CAD and left ventricular damage, the presence of unstable angina, postinfarction angina or exercise tests markedly positive for ischemia (with or without chest pain) is now recognized as an adverse clinical sign. Few studies provide prognostic information for totally asymptomatic patients with CAD. In the U.S. Air Force study[3] of asymptomatic men with active ischemia by treadmill or radionuclide studies, a yearly mortality of 17% was noted. In both the National Institutes of Health[4] and Duke–Harvard studies[5] in mixed populations of symptomatic and asymptomatic patients, a considerable yearly mortality rate of up to 2 to 3% was found in the asymptomatic group overall. Many of these studies, however, were conducted in populations in which symptoms were both absent and present and have not emphasized whether there was evidence of continuing myocardial ischemia.

Fewer studies have addressed the prognostic implications of transient ischemia in patients with angina. Bonow et al[6] reported on patients with mild symptoms, ejection fractions at rest ≥40% and 3-vessel CAD. Those patients who had no objective evidence of transient regional myocardial ischemia on ECG or radionuclide ventriculogram had an excellent 4-year prognosis when contrasted with a comparable group with evidence of ischemia. These clinical markers of underlying transient myocardial ischemia (whether associated with pain or not) may represent a common pathophysiologic event resulting in damage to heart muscle and poorer prognosis quite apart from the extent of coronary disease and ventricular damage.

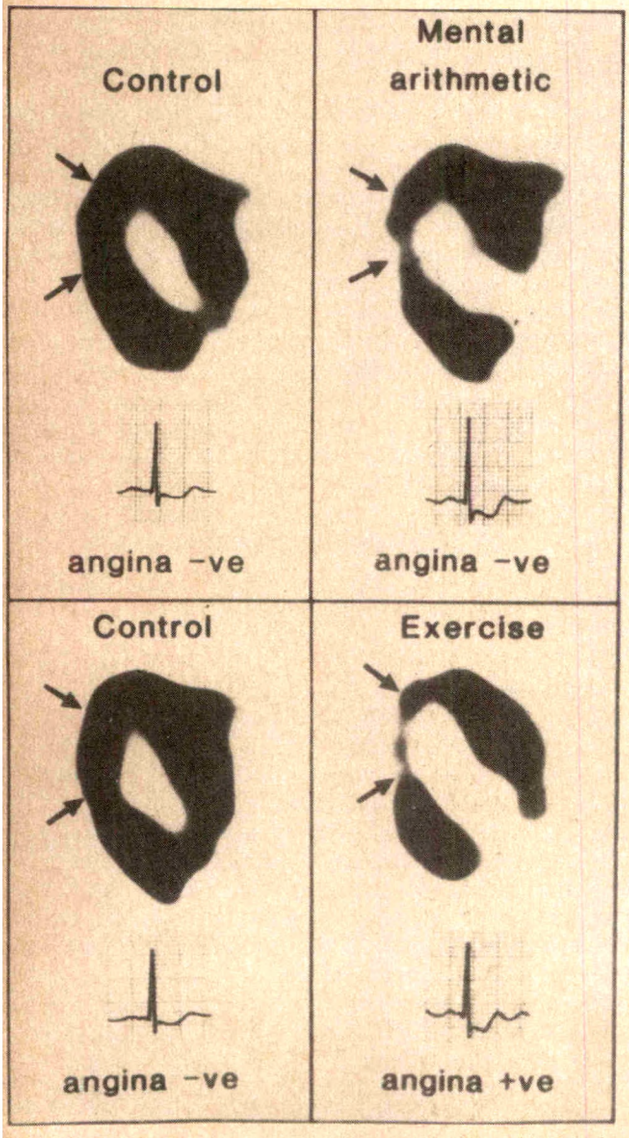

FIGURE 1. Regional myocardial perfusion assessed by positron emission tomography measuring rubidium-82 uptake. Left ventricle is shown with the mitral orifice posteriorly placed; **arrows** indicate the anterolateral wall of the left ventricle. Mental arithmetic caused a regional decrease in coronary blood flow, with silent ST-segment depression indicating ischemia. Later this abnormality recovered but was reproduced by supine exercise and associated with angina.

Transient Regional Myocardial Ischemia

Experimental and clinical research have both described in detail the sequence of events during episodes of transient ischemia: immediate failure of contractile function is followed by abnormalities of rhythm and electrocardiographic disturbances. On a biomechanical level, tissue oxygen and pH fall with failure of β oxidation, temporary preference for glycolysis and eventually, lactate accumulation. With time, membrane function and structure fail. These events have been characterized clinically in the hospital with the ECG, radionuclide ventriculography, thallium-201 imaging and positron emission tomography with substrates used as tracers.

Combining these techniques for detection of transient regional ischemia with such provocations as exercise, dipyridamole, ergonovine and exposure to cold has provided diagnostic and, recently, prognostic information regarding the presence of CAD. Deanfield et al[7,8] have studied patients with chronic stable angina, positive exercise tests for ischemia and known CAD with positron emission tomography. They have assessed regional myocardial perfusion using uptake of rubidium-82. They found perfusion defects in the same myocardial segments during both painful and painless episodes of ST-segment depression associated with exercise, cold exposure, mental arithmetic and cigarette smoking, as well as without provocation (Fig. 1). This evidence suggests that transient episodes of ST-segment depression do represent ischemic episodes in these patients and occur with activities associated with daily living. If the activity of transient ischemia affects clinical status and prognosis, then we need to know the trigger mechanisms, frequency and duration of events out of hospital.

New Clinical Features of Ischemic Activity

Twenty-four hour ambulatory monitoring of the ECG in patients with angina, exercise-induced ischemic ST-segment depression and proven CAD has been carried out in a number of research centers.[9–11] The results show that most episodes of myocardial ischemia as manifested by ST-segment depression during daily activity are asymptomatic (68 to 76%). The episodes are surprisingly prolonged; the median duration is 5 to 8 minutes and the range is from 1 to >60 minutes. Another striking finding in all these studies is that a large proportion of asymptomatic episodes occur during rest or are associated with such modest physical activities as eating, driving, light housework and mental arousal (Fig. 2). Deanfield et al[9] have shown that approximately one-half of these events have little or no increase in heart rate at the onset of ischemia and that the distribution of heart rates at onset of ST depression during ambulatory monitoring is lower than that seen in the same patients during exercise testing.

We recently demonstrated a significant circadian variation in the number and duration of ischemic episodes with a marked increase in ischemic activity during the first 4 to 6 waking hours of the day. The difference does not appear to be due to increased physical activity in the morning hours or markers of myocardial demand such as increased heart rate at onset of ST depression. These findings suggest that alterations in coronary tone and supply may be responsible for this morning peak in ischemic activity.

An increasing number of asymptomatic men undergo treadmill exercise and the "silent positive exercise test" indicates that myocardial ischemia remains a vexing clinical problem in these subjects. Ambulatory monitoring of the ECG has shown that most of these patients do indeed have multiple episodes of transient ischemia out of hospital. In addition, our data indicate that these ischemic events have all the same characteristics found in patients with angina (i.e., painless episodes, little or no tachycardia preceding events, prolonged duration and circadian rhythm).

Clinical Implications

A number of studies from major centers have demonstrated that silent myocardial ischemia in patients with CAD is more common than previously appreciated. At the same time, the activity of transient ischemia seems to be emerging as an adverse finding as it relates to prognosis. Although management with drugs, angioplasty and coronary bypass surgery are directed toward relief of symptoms, they are also used in an attempt to prevent or reverse the disturbances in coronary blood flow and ischemia that threaten ventricular myocardium. This new information about the characteristics of transient ischemia during daily activity suggests that important information regarding the activity of disease may be missed with assessment of symptoms and exercise response only.

Thus, a number of questions regarding therapeutic aims have been raised. Is it important to suppress all ischemic activity apart from the initial necessary step of relieving symptoms? Do the currently used dosage regimens of drugs take into account the circadian variation of ischemia and the surge of activity in the morning? What are the differential effects of various drugs on the different types of transient ischemia seen out of hospital? Will the activity of transient ischemia help to identify high-risk groups who require more aggressive evaluation and treatment?

With ambulatory electrocardiographic recording it is possible to quantitate previously unnoticed episodes of disturbed regional myocardial perfusion and correlate these with the activities provoking them. It seems unlikely that transient regional myocardial ischemia in any form can be dismissed as unimportant. However, caution is suggested before the wide-scale application of ambulatory monitoring in the assessment of CAD occurs. Most studies have been done in relatively homogenous groups with symptomatic coronary dis-

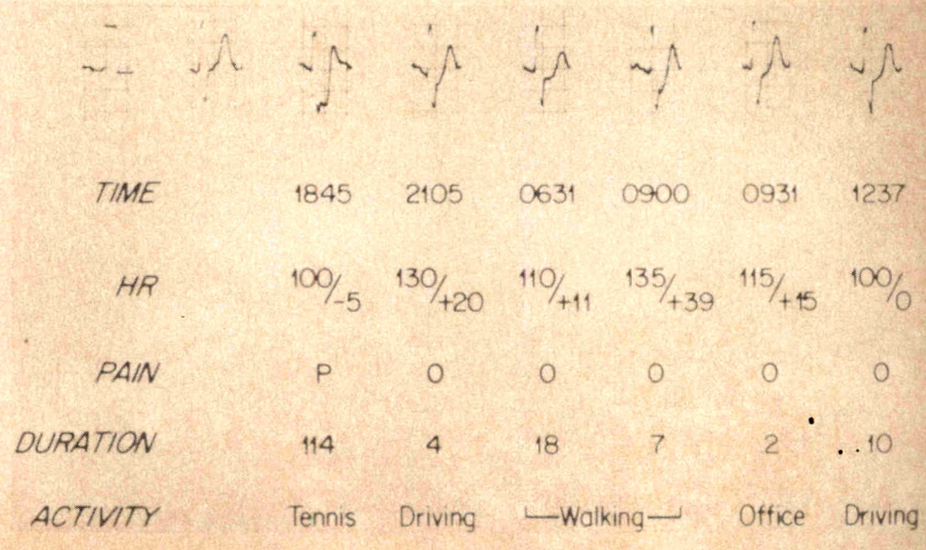

FIGURE 2. A typical 24-hour ambulatory electrocardiographic recording in a 61-year-old man showing electrocardiographic complexes from 6 episodes of transient ischemia, only 1 of which was accompanied by angina. The time of each episode and the heart rate (HR) at onset and change in HR 1 minute before onset are shown below each episode. Three of the events were prolonged, lasting for 10 minutes or longer. Most episodes were associated with ordinary everyday activity.

ease. The prevalence of silent transient ischemia and the sensitivity and specificity of ambulatory ST-segment depression to detect ischemia in a more heterogenous population are unknown. The day-to-day variability and natural history of exacerbations and remissions in disease activity must be considered when assessing the effect of an intervention on ambulatory ischemia. Prospective studies and clinical trials will be needed to answer these questions.

In summary, in the natural history of coronary atherosclerosis, 25 to 30% of myocardial infarctions and sudden deaths are silent or unexpected manifestations of coronary heart disease. To this we can now add ambulatory transient ischemia, which appears to be common, surprisingly prolonged and associated with ordinary daily activities. The underlying transient decreases in regional coronary flow suggest that the activity or reactivity of atherosclerotic and stenosed epicardial arteries plays a causative role and needs more attention. If clinical research shows that this ischemic activity is undesirable, then the goals of treatment must change. The practitioner may have to modify his approach to assessment and management of these patients by seriously considering the activity and characteristics of ischemic heart disease out of hospital and during daily life in an attempt to procure lasting relief of symptoms and prevention of ischemic damage.

Mechanisms and Therapy of Silent Myocardial Ischemia and the Effect of Transdermal Nitroglycerin

WILLIAM E. SHELL, MD

Studies of the mechanisms and characteristics of ischemic heart disease have increasingly documented evidence of myocardial ischemia in the absence of symptoms. Recent work using objective criteria of ischemic events has confirmed that angina pectoris or its equivalents need not accompany true myocardial ischemia, and this appears to be quite common. The impact of these findings on prognosis awaits further study, but preliminary data suggest an improved prognosis for persons in whom coronary artery disease remains asymptomatic compared with symptomatic patients. Further, reduction of silent ischemic events with nitrate therapy may be associated with a more benign subsequent course. Preliminary trials show a reduction of the number, duration and magnitude of silent ischemic events by transdermal nitroglycerin. Ongoing technical innovations in monitoring systems should allow more complete characterization of this syndrome and lead to definition of medical therapy for it. (Am J Cardiol 1985;56:23I–27I)

Several acute ischemic syndromes have recently been defined in terms of their pathophysiology, and this has facilitated the choice of more specific therapy. For example, the recognition that transmural acute myocardial infarction represents an occlusive clot in a main coronary artery[1] has led to the use of either streptokinase or tissue plasmin activator as fibrinolytic therapy.[2,3] In addition, nontransmural acute myocardial infarction, unstable angina pectoris, stable exertional angina pectoris, stable spontaneous angina and variant angina pectoris have also been defined. A new syndrome—silent myocardial ischemia—has also been noted. This article will focus on selected aspects of silent myocardial ischemia and will discuss the use of transdermal nitroglycerin to control the number, duration and magnitude of ischemic events.

Definition of Acute Ischemic Syndromes

Transmural myocardial infarction is a syndrome associated with chest pain, ST-segment elevation, Q-wave evolution and appearance of cardiac enzyme activity in plasma. DeWood et al[1] have demonstrated that this syndrome is associated with an occlusive clot in 87.3% of patients with transmural myocardial infarction, although Oliva et al[4] have shown that spasm of the coronary artery can cause transmural acute myocardial infarction in selected patients. In the Framingham experience,[5] 15% of transmural myocardial infarction occurred silently. Further, the incidence of silent myocardial infarction appears to be 3.6/1,000 adults compared with an incidence of 5.3/1,000 symptomatic infarcts.[6] Thus, silent transmural myocardial infarction appears to be a frequent event.

The precipitating events leading to nontransmural acute myocardial infarction are the least well known of the acute ischemic syndromes. The syndrome, which consists of chest pain, ST-segment changes on the electrocardiogram and the appearance of cardiac enzyme activity in plasma, is initiated by an admixture of clot, spasm, platelet aggregation and inappropriate myocardial oxygen demand. The incidence of silent nontransmural acute myocardial infarction is unknown, but autopsy evidence suggests that between 20 and 60% of acute myocardial infarctions are symptomatic.[7] Thus, silent nontransmural acute myocardial infarction may be quite common.

Stable exertional angina pectoris was described by Heberden in 1772. The classic syndrome of exertional chest pain relieved by rest and nitroglycerin is caused by an increase in myocardial oxygen demand, which outstrips flow through fixed coronary arterial obstruction. Even in this classic syndrome, silent events have been described. It is well known that silent ST-segment depression frequently occurs during exercise testing in patients with established coronary arterial obstruction. In addition, silent ST-segment depression during spontaneous exertion has been described

using Holter monitoring. Cecchi et al,[8] for example, have described silent ST-segment depression with exertion in patients with classic exertional angina documented by ambulatory monitoring. They found that the silent events were more frequent than the symptomatic events. These observations support an earlier report by Coccol et al[9] that showed that silent ischemic events induced by exertion are more frequent than symptomatic events in patients with classic exertional angina.

Spontaneous angina pectoris is a syndrome associated with chest pain and reversible ST-segment depression. The symptoms occur at rest with emotion or with minimal activity. This syndrome is characterized by the poor correlation of symptoms with an increase in myocardial oxygen demand. The syndrome has been called unstable angina, angina at rest, emotional angina, coronary insufficiency and preinfarction angina,[10–14] depending on the particular characteristic under discussion. The term "spontaneous angina" will be used here to stress the lack of correlation of external events with an increase in myocardial oxygen demand and the potential initiating mechanisms. The incidence of silent events in this syndrome is incompletely defined but appears to be quite significant. Biagini et al[15] documented 520 episodes of ST-segment changes in 11 patients who fit the profile of spontaneous angina, and only 12% of the episodes were symptomatic.

Spontaneous Angina: A Disease of Decreased Myocardial Oxygen Supply

A specific sequence of changes occurs in patients with spontaneous angina. The sequence includes ST-segment alteration (either elevation or depression), increase in pulmonary artery pressure, increase in blood pressure and finally chest pain. The chest pain is a relatively late event in the sequence of the ischemic process.[16] Also, it can be demonstrated that coronary sinus oxygen saturation decreases before the ST-segment changes,[17] indicating that regional perfusion falls before the ischemic event. In most instances of spontaneous angina, ischemia precedes the increase in myocardial oxygen demand.

Because the onset of ischemia precedes the onset of increased oxygen demand, spontaneous angina must be associated with a reduction in oxygen supply as the initiating event. The fall in oxygen saturation in the coronary sinus in the early moments of the event[17] and before the ST-segment alteration further confirms the decrease in regional perfusion associated with a spontaneous anginal event. A primary decrease in coronary blood flow appears to be the initiating event in the cascade of temporal changes associated with spontaneous ischemic events.

The discussion of spontaneous ischemia and the subsequent discussion of spontaneous silent ischemia depend on the assertion that ST-segment alterations reliably reflect ischemic events. Although not completely understood in all situations, recent evidence suggests that, in patients with atherosclerotic coronary artery disease (CAD), the overwhelming proportion of ST-segment events indicate ischemia. For example, Maseri et al[18] have shown that patients with spontaneous ST-segment depression demonstrate a thallium defect, which occurs during the periods of ST-segment change both with and without chest pain. Recently, Deanfield et al,[19] using rubidium imaging and positron emission tomography, have shown that spontaneous ST-segment events, both symptomatic and asymptomatic, are invariably associated with a reduction in regional perfusion. In patients with CAD, there is little evidence that sustained ST-segment alterations >60 seconds occur without a reduction in regional blood flow.

Potential mechanisms that could initiate intermittent reduction of regional blood flow include spasm of the coronary artery,[20] platelet aggregation with subsequent displacement or lysis of the platelet clot[21] and alteration of coronary artery distending pressures.[22] These mechanisms occur in diseased coronary arteries, providing a physiologic basis for initiation of episodes of spontaneous reduction in blood flow.

Spontaneous angina reflects intermittent reduction of coronary blood flow. It is a disease of reduced blood flow and not of increased myocardial oxygen demand. Prevention and treatment of spontaneous ischemic events should be planned with an understanding of these pathophysiologic mechanisms.

Silent Myocardial Ischemia: Definition and Demonstration

Silent myocardial ischemia can be defined as the presence of objective evidence of ischemia without accompanying symptoms in patients with anatomically significant CAD.[23] This definition can be expanded to include objective evidence of ischemia in patients both with and without coronary atherosclerotic obstruction—again occurring without symptoms. Several objective markers of imbalance between myocardial oxygen demand and supply have been proposed, including anatomic obstruction to flow, electrocardiographic changes, distribution of radioactive tracers or coronary blood flow[24] and biochemical indicators of inadequate blood flow.[25] Each of these markers has been used to document the existence of the ischemic process unaccompanied by the pain of angina pectoris.

Hemodynamically significant CAD has been repeatedly documented in asymptomatic patients. In one review, Diamond and Forrester[26] indicated that asymptomatic CAD existed in 4.5% of patients autopsied after death from noncardiac causes. Erikssen et al[27] documented hemodynamically significant CAD with angiography in 3.4% of a group of asymptomatic and presumably healthy men. Froelicher et al[28] found significant CAD with angiography in 2.4% of his cohort of asymptomatic U.S. Air Force men. Cohn analyzed these data and reported an overall population rate of asymptomatic yet hemodynamically significant CAD between 2 and 5%.[23]

Asymptomatic ischemia has been detected by continuous ambulatory electrocardiographic monitoring, using alterations of the ST segment as the marker of the myocardial ischemia. In 1974, Stern and Tzivoni,[29] using high-fidelity Holter recording systems, studied

80 patients with symptoms of angina pectoris; 37 patients demonstrated ST-segment changes during the monitoring period. In 24 of the 37 patients, ST-segment change occurred both with and without symptoms. Symptomatic events in this cohort of 24 patients were usually associated with ST-segment alterations. Importantly, 13 of the 37 patients experienced episodes of ST-segment alteration without chest pain. This study suggested that in patients with anginal episodes, asymptomatic episodes of ST-segment changes frequently occur.

Schang and Pepine[30] in 1977 reported that 75% of the episodes of ischemic ST-segment depression on continuous ambulatory electrocardiographic monitoring in their patients with CAD were asymptomatic and that 72% of these asymptomatic events occurred at rest or with minimal activity. Moreover, hourly nitroglycerin significantly decreased the frequency of these episodes, supporting the concept that these events represent painless ischemia. Coccol et al[9] found ST-segment changes in 22 of his 40 patients with CAD and stable effort angina. Most of the events were asymptomatic; the symptomatic events were less frequent but lasted longer than the asymptomatic ones. Cecchi et al[8] described 32 patients with established CAD and effort angina who had ST-segment depression on continuous ambulatory electrocardiographic monitoring; 8 of these patients always had pain with ST-segment depression, no patient ever had pain with ST-segment change and 15 had both symptomatic and asymptomatic events. In the last group of patients, both the duration and extent of ST-segment depression were greater when accompanied by angina. Recently, Nademanee,[31] and Deanfield[32] and their co-workers, using quantitative systems for analyzing continuous ambulatory electrocardiographic monitoring, demonstrated that between 70 and 80% of ST-segment events in patients with established CAD occur without symptoms. These observations suggest that silent ST-segment alterations are frequent in patients with established CAD, probably reflecting recurrent silent ischemic events in such patients.

Silent ischemic events may also occur in patients with angiographically normal coronary arteries, reflecting either spontaneous increases in coronary vascular tone or inordinate increases in myocardial oxygen demand. Guazzi et al[33] described, in a single patient, episodes of silent ST-segment alterations with hemodynamic changes consistent with anginal episodes; the patient had angiographically normal coronary arteries. Masseri[16] in 1978 performed continuous ambulatory electrocardiographic monitoring in patients with angina at rest and noted a large number of transient ST-segment alterations; 10% of these patients had angiographically normal coronary arteries. These studies suggest that transient ischemic events can occur in patients without obstructive CAD.

ST-Segment Alterations as a Marker of Myocardial Ischemia

Several investigators have urged caution in the use of ST-segment depression during continuous electrocardiographic monitoring as a marker of asymptomatic myocardial ischemia for several reasons, including nonischemic induction of ST-segment changes and artifact induced by recording systems. Armstrong et al,[34] using 2-channel system (Avionics) and an unknown duration of ST-segment alteration as an index, reported >1 mm of ST-segment depression in 15 of 50 normal asymptomatic subjects. The episodes lasted 30 seconds to 2 hours, but there were no subsequent stress electrocardiographic abnormalities or morbid events during the 36 month follow-up period.

Crawford et al,[35] using single-channel recording system (Avionics) and a 3-beat criterion, reported a 39% false-positive rate when comparing ST-segment depression on continuous ambulatory electrocardiographic monitoring with angiography.

Suggested causes of ST-segment depression in the absence of myocardial ischemia include dynamic changes in autonomic tone, electrolyte abnormalities, various drugs, cerebrovascular disease,[35] hyperventilation, large carbohydrate meals, orthostatic position changes, mitral valve prolapse, neurocirculatory asthenia[36] and thermal, physical and emotional stress.[37] These episodes tend to be prolonged, with gradual onset and gradual regression. However, most investigators, including Armstrong and Morris,[36] have clearly considered silent ST-segment depression to reflect myocardial ischemia in patients with typical angina and probably to reflect ischemia in patients with known CAD. Substantial work with true normal subjects using artifact-free recording systems will be required to assess the incidence and implications of silent spontaneous ST-segment depression in otherwise normal subjects. Our own experience—using a calibrated real-time recording system and a 60-second ST-segment criterion and characterization of ST-segment changes with discrete onset and offset as indicative of ischemia—suggests that ischemic ST-segment events in normal subjects without prolapsed mitral valve are very infrequent.

Maseri et al,[16] concerned with the implication of spontaneous ST-segment depression as a marker of ischemia in patients both with and without atherosclerotic vascular disease, have investigated the implication of these changes. In 7,000 continuous electrocardiograms in patients with a history of spontaneous angina, with and without angiographically defined CAD, they noted numerous typical ST-segment changes not associated with anginal pain. A large number of asymptomatic ST-segment changes were accompanied by hemodynamic left ventricular dysfunction and by regional reduction of myocardial perfusion demonstrated by thallium scanning. Chierchia et al[38] have shown that silent ST-segment changes are preceded by regional myocardial blood flow reduction, based on continuous monitoring of coronary sinus oxygen saturation. Maseri et al[16] have also shown the association of asymptomatic transient ST-segment changes with angiographically defined vasospasm in patients with and without coronary artery disease. Finally, Deanfield et al,[19] using rubidium imaging with positron emission tomography, have demonstrated

that each episode of ST-segment alteration is associated with a decrease in regional perfusion of the myocardium. To date, there has not been a demonstration that a spontaneous ST-segment change >60 seconds in patients with CAD occurs in the absence of a reduction of coronary blood flow.

Thus, while the usefulness of the ST-segment change as a marker of myocardial ischemia in completely asymptomatic normal persons without CAD may still be in some doubt despite ongoing technical innovations in monitoring techniques, ST-segment abnormalities in patients with previous anginal symptoms or a history of CAD seem to represent myocardial ischemia, even in the absence of angiographically defined disease or pain during a given ST-segment event.

The Prognostic Implications of Silent Myocardial Ischemia

The prognosis of silent myocardial ischemia is poorly defined; both an increased mortality secondary to a defective anginal warning system and a decreased mortality related to a smaller potential ischemic zone have been proposed.[23] Cohn et al[39] have followed a group of 127 symptomatic patients and a smaller cohort of 44 asymptomatic patients with similar CAD for more than 7 years. The survival at 7 years was 81% in the asymptomatic group compared with 62% in the symptomatic group; the yearly mortality was 2.7 compared with 5.4%, respectively. In the patients with 3-vessel disease, the yearly mortality rate in the asymptomatic group was 4.7% compared with 8.7% in the symptomatic group. This suggests an intermediate prognosis for silent ischemia in persons with symptomatic CAD compared with those without CAD. This study represents the largest cohort of asymptomatic subjects followed; however, not all of the asymptomatic patients had had documented silent myocardial ischemic events. Clearly, further data are necessary concerning the natural history and prognostic implications of silent myocardial ischemia and the effects of therapeutic reduction in the frequency of silent ischemic episodes. In addition, there is a paucity of data defining the outlook for patients with angina who also demonstrate silent myocardial ischemic events; our initial experience suggests that these patients have an adverse short-term prognosis in the absence of therapy.

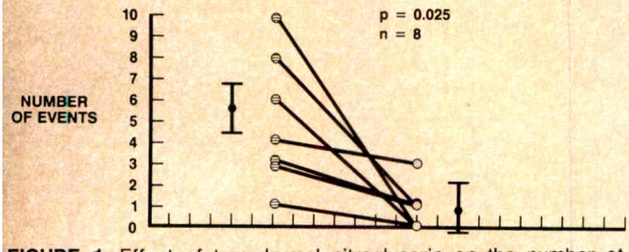

FIGURE 1. Effect of transdermal nitroglycerin on the number of ischemic events. Both symptomatic and asymptomatic events are included in number of events. ⊖ represents patients before therapy; ⊙ represents patients after stabilization on transdermal nitroglycerin.

The Abolition of Silent Ischemia by Nitrates

The treatment of silent ischemic events is largely unexplored. There are a number of potential agents that could abolish these events, including nitrates, β-blocking agents, calcium-channel blocking agents and coronary bypass surgery. We have been examining the use of transdermal nitroglycerin in the syndrome of silent myocardial ischemia. There were several reasons for the choice of this agent. The nitrates have a long history in the treatment of spontaneous anginal events, and silent ischemia is analogous to spontaneous angina. Transdermal nitroglycerin could provide nearly constant blood levels, which may be necessary in patients with silent ischemia because they do not know when they experience ischemic events. In addition, the nitrates have a known safety range without decreasing myocardial contractility, so we could titrate to large doses if necessary to treat the silent events.

Schang and Pepine[30] studied the effects of sublingual nitrates compared with placebo on the frequency of silent myocardial ischemic events. Five patients were treated with either hourly sublingual nitroglycerin or placebo during 10-hour periods of ambulatory monitoring. Asymptomatic episodes of ST-segment depression were significantly less frequent with nitrate therapy than with placebo (3.7 compared with 0.6 episodes per monitoring period).

We have recently completed an open label trial to test the effects of transdermal nitroglycerin on the

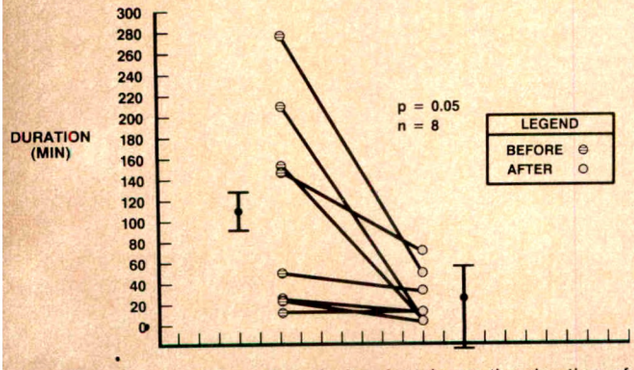

FIGURE 2. Effect of transdermal nitroglycerin on the duration of ischemic events.

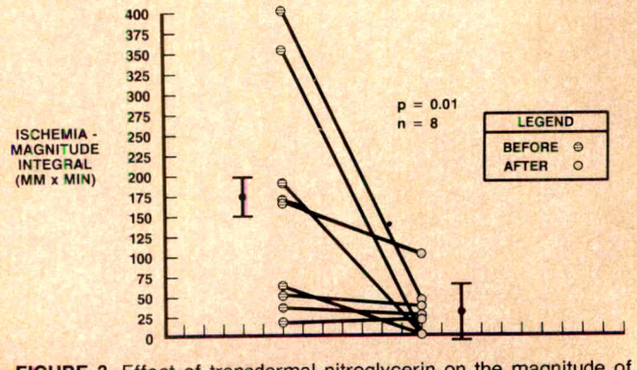

FIGURE 3. Effect of transdermal nitroglycerin on the magnitude of ischemic events as estimated by the ischemia-magnitude integral.

number, duration and magnitude of ischemic events.[40] In 8 patients with chronic stable angina, we performed 24-hour ambulatory monitoring using a calibrated system (DMI Instruments). From each tape a 24-hour full disclosure record was displayed on hard copy. From the hard copy printout, the onset and offset of each ST-segment event (either depression or elevation) were marked. In addition, the maximal depth of either the depression or elevation was measured in millimeters. We then counted the number of events, measured the duration in total minutes and estimated the magnitude of each event by multiplying the duration by the magnitude for each event—the so-called ischemia-magnitude integral. The baseline 24-hour tape was obtained while patients were receiving β blockade and sublingual nitroglycerin. Each patient was experiencing symptomatic angina pectoris on the regimen of β blockade and sublingual nitroglycerin.

We then titrated the dosage of transdermal nitroglycerin in each patient, beginning with 5 mg/24 hours (10 cm^2) and increasing the dose in 5 mg/24 hour increments. We increased the dosage until the number of symptomatic events was abolished and the 24-hour tape was repeated. The mean dosage was 10.4 mg/24 hours (range 5 to 20 mg or 10 to 90 cm^2). The number of symptomatic events decreased in all 8 patients. In addition, the total number of events fell from 5.8 to 0.9/24 hours (Fig. 1, $p < 0.025$). As in other studies, 80% of the events were silent.

The duration of ischemic events also decreased from 110 to 21 minutes/24 hours (Fig. 2, $p < 0.05$). The magnitude of the ischemia as estimated by the ischemia-magnitude integral also decreased (Fig. 3, $p < 0.01$).

Thus, in an open label trial, using a titration protocol, transdermal nitroglycerin reduced the number, duration and magnitude of both symptomatic and asymptomatic ischemic events. We are currently performing a double-blind, placebo-controlled trial to confirm these initial results. In addition, we are assessing the impact of attenuation by the time of this therapeutic result. Each of the agents that could potentially reduce the number of ischemic events defined by ambulatory monitoring should be subjected to rigorous examination. Our initial results with transdermal nitroglycerin are promising and suggest a role for these agents in controlling silent myocardial ischemia.

In summary, silent myocardial ischemia is a common manifestation of ischemic heart disease and occurs in all the ischemic syndromes. The current diagnostic standard for silent ischemia involves ambulatory monitoring. There is a paucity of data concerning the treatment of silent ischemic events. Our initial data suggest that transdermal nitroglycerin given in sufficient doses can reduce the number, duration and magnitude of ischemic events.

Nitrate Tolerance

JOHN O. PARKER, MD

Nitrate tolerance may be defined as that condition in which increasing nitrate doses are required to induce a given hemodynamic or antianginal effect. Tolerance may be due to changes in pharmacokinetics or to alterations in the property of target tissues, making them less sensitive to the nitrate effect. The question of nitrate tolerance has been addressed using 4-times-a-day therapy with oral isosorbide dinitrate, daily therapy with long-acting isosorbide dinitrate ointment and once-a-day therapy with nitroglycerin patches. Each of these treatment modalities is associated with initial beneficial effects, but during sustained therapy, there is marked attenuation of the effect both in magnitude and duration. Thus the concept that stable nitroglycerin blood levels over 24 hours are desirable appears to be incorrect. Preliminary hemodynamic studies suggest that short periods of nitrate withdrawal restore the hemodynamic effect of the nitrates, and it is postulated that intermittent nitrate therapy may be desirable in the management of angina. Transmucosal nitroglycerin administration for a 15-hour period with a 9-hour washout period was recently undertaken. The results demonstrated that this method of nitrate administration is not associated with development of tolerance to its antianginal effects.

Large doses of transdermal nitroglycerin, varying from 45 to 100 mg during short-term studies, have been shown to result in only minimal increases in exercise tolerance at 24 hours. These findings, plus evidence that with smaller doses tolerance occurs after only 1 week of once-a-day therapy, challenge the concept that larger nitroglycerin dosages, administered once a day by transdermal patches, could be effective throughout a 24-hour period in patients with angina pectoris. The current information suggests that it would be necessary to apply larger doses, but to remove them after a period of 12 to 14 hours and allow a washout period to prevent tolerance.

(Am J Cardiol 1985;56:28I–31I)

Nitrate tolerance may be defined as that condition in which increasing nitrate doses are required to induce a given hemodynamic or antianginal effect. Tolerance may be due to changes in pharmacokinetics or to alterations in the property of target tissues, making them less sensitive to the nitrate effects. There is substantial evidence of the development of tolerance to the organic nitrates. This has been demonstrated in munitions workers,[1] patients with angina pectoris[2,3] and patients with left ventricular dysfunction.[4] The fall in systolic blood pressure after the administration of nitrates has been shown to be markedly attenuated during sustained therapy in animals,[5] patients with angina[3] and patients with heart failure.[4] The effect of these agents on left ventricular filling pressures in cardiac failure persists during sustained therapy, but the magnitude of response is diminished.[4,6]

There has been substantial controversy as to the relevance of hemodynamic tolerance to the antianginal effects of the organic nitrates. Clinical studies have reported prolongation of exercise times for periods of several hours after oral isosorbide dinitrate (ISDN) during sustained therapy.[7,8] Our studies have repeatedly shown that during 4-times-a-day oral therapy with ISDN, the antianginal effects persist for only 1 to 2 hours, rather than the 8 hours seen during acute dosing.[2,3,9] The basis for these conflicting observations is not clear but may be related to study design.

Tolerance to Isosorbide Dinitrate

Twelve male patients with chronic stable angina entered a placebo-controlled, double-blind study in which the hemodynamic and antianginal effects of ISDN were studied during short- and long-term therapy.[2] During the short-term phase, each patient was

studied twice a week with at least 2 days separating study days. Following preliminary treadmill exercise testing, patients were given identical-appearing tablets that contained either placebo or ISDN in doses of 15, 30, 60 or 120 mg. Each patient received placebo on 2 occasions. Investigations were carried out in the morning; patients were in the fasting state and heart rate and blood pressure were recorded in the supine and standing positions. Patients then performed treadmill testing, and the times to the onset of angina and development of moderate angina were recorded. Immediately after this control test, the scheduled medication was administered, and resting hemodynamic indexes were measured and treadmill exercise was performed after 1, 2, 4, 6 and 8 hours. All 12 patients received 15, 30 and 60 mg of ISDN, but only 7 received the 120-mg dose in this short-term phase, as headache or hypotension developed with 60 mg in 5 patients.

After completion of the short-term phase, patients were placed on placebo tablets 4 times a day for 2 weeks. At the end of this period, hemodynamic and treadmill exercise testing were carried out before and 8 hours after the final morning dose of placebo. In consecutive weeks, patients received 15, 30, 60 and 120 mg of active ISDN 4 times a day (at 8 AM and 12, 4 and 8 PM). At the end of each of these treatment periods, the patients came to the laboratory without taking the morning medications. Treadmill exercise testing was performed, the scheduled dose of ISDN administered and then hemodynamic and treadmill exercise testing performed over an 8-hour period.

During short-term therapy with each dose of ISDN, systolic blood pressure dropped at 1 hour and remained below placebo values for the 8-hour observation period. There was an apparent dose-response relation with greater decreases in systolic blood pressure with the higher doses. This hypotension was accompanied by reflex increases in heart rate. During long-term therapy, each dose of ISDN produced a reduction in systolic blood pressure at 1, 2 and 4 hours, but not at 6 or 8 hours. There was no apparent dose-response relation.

During the short-term study, significant prolongation of treadmill exercise time to the onset of angina and development of moderate angina was seen with each dose of ISDN. This effect, which was greater with the larger doses, was apparent over the entire 8-hour observation period. During long-term, 4-times-a-day therapy, exercise times to the onset of angina and development of moderate angina were prolonged for only 2 hours after each dose, and thereafter, there was no difference compared with placebo. The magnitude of the improvement seen at 2 hours was less pronounced than that seen during short-term therapy. The attenuated hypotensive and antianginal effects occurred despite the presence of significantly higher plasma ISDN concentrations during the long-term compared with the short-term study.

Since this initial observation, we have completed further studies that have confirmed the development of tolerance: treadmill exercise time is prolonged for 2 hours after a given dose, but no effect is seen thereafter.[3,9]

Tolerance to Transdermal Isosorbide Dinitrate

In a recent study, we documented the development of tolerance to other modes of ISDN administration.[10] Twelve patients were studied after the single application of 100 mg of ISDN ointment spread over a 200 cm^2 area. This preparation was formulated to provide an effect over a 24-hour period. This investigation showed that treadmill walking time was prolonged for 8 hours after a single application, but there was no effect at 24 hours. When similar doses were applied once a day for a period of 7 to 10 days, treadmill walking time over the 8-hour period was identical to that seen with placebo ointment. This was further confirmation of the rapid development of tolerance during long-term therapy. When sublingual nitroglycerin (NTG) was administered, a normal hypotensive response was seen and there was a marked improvement in treadmill walking time.

Tolerance to Transdermal Nitroglycerin

NTG ointment has been used for several years for the management of patients with angina[11] and congestive heart failure.[12] Studies have shown prolongation of treadmill walking time for periods of 3 to 7 hours[11,13] with this product, but little information is available regarding long-term therapy. Reichek et al[11] studied a small subgroup of patients after several months of 3-times-a-day therapy with NTG ointment and found no attenuation of the antianginal effects. There are, however, no well-controlled studies that have assessed the antianginal effect of NTG ointment during long-term therapy.

NTG patches have been available for approximately 3 years in the United States and they have received widespread clinical acceptance. The patches are designed to provide a steady infusion of NTG and to lead to stable plasma concentrations over the 24-hour dosing interval. The early studies claimed that patches delivering 5 mg over 24 hours induced plasma NTG concentrations of approximately 1 ng/ml.[14] Subsequent investigations have not confirmed this; generally, the patches produce much lower plasma levels.[15]

Clinical studies have shown that during short-term therapy with NTG patches, exercise tolerance is prolonged for periods ranging from 4 to 8 hours, but with the usual doses used, there have been no reports of prolongation for longer periods throughout the 24 hours.[15,16] In a group of 6 patients who received 45-mg patches, we did show a 24-hour effect during short-term therapy (Fig. 1), but no data are available regarding long-term therapy.[15] In an uncontrolled study, we observed 4 patients before and after applications of 50- to 100-mg NTG patches and found effects at 12 and 24 hours in 3 patients.

We have demonstrated that during long-term therapy there is attenuation of the antianginal effects with

the currently available doses of transdermal NTG. Thus, after 7 to 10 days of once-a-day therapy with NTG patches that deliver 15 mg/day, treadmill walking time throughout the testing period was similar to that seen with placebo.[15]

It would appear from the data from oral ISDN, transdermal ISDN and transdermal NTG studies that long-term therapy with each of these nitrate preparations is associated with diminution of the hemodynamic and antianginal effects. The complete lack of efficacy of transdermal ISDN and transdermal NTG during long-term therapy suggests that the concept of providing steady-state plasma levels for continuous antianginal protection is incorrect.

Rate of Tolerance Development

The studies just outlined have demonstrated that tolerance to the antianginal effects of the nitrates occurs within 7 to 10 days of sustained therapy. There is little information regarding the minimal period of time required for such tolerance to develop in man.[17] We used a challenge with 5 mg of sublingual ISDN to assess nitrate responsiveness (Fig. 2). On day 1, the effect of sublingual ISDN (5 mg) on heart rate and systolic blood pressure was assessed over a 3-hour period. Patients then received 15 mg of ISDN every 6 hours for 48 hours. On day 2, after only 3 tablets of ISDN, the hypotensive effect of sublingual ISDN was attenuated. The reduction in systolic blood pressure was approximately 50% of that present during the control study day. A similar pattern was seen on the third day, 48 hours after the institution of oral ISDN therapy. Patients were then placed on oral ISDN placebo, and on day 4, when they had received only 3 placebo tablets, the blood pressure response to sublingual ISDN was similar to the control values. The response persisted on day 5. This study demonstrated that within less than 24 hours there was evidence of hemodynamic tolerance, and that within less than 24 hours of withdrawal of oral ISDN the hemodynamic response to the ISDN challenge was normal.

Is Intermittent Nitrate Therapy Less Likely to Be Associated with Nitrate Tolerance?

As demonstrated, the delivery systems designed to produce steady-state nitrate levels are associated with complete loss of antianginal efficacy in a short period of time. When oral medications are given 4 times a day, the antianginal effect is diminished but is still evident. It has been suggested that a period of drug washout might prevent the development of tolerance. We assessed this by comparing the antianginal effects of oral ISDN administered 4 times a day with transmucosal NTG administered 3 times a day, which provided a 9-hour washout period overnight.[9] This study confirmed the development of tolerance during sustained, 4-times-a-day therapy with ISDN. This study showed that treadmill walking time was prolonged 1 hour after a given oral ISDN dose, but no subsequent effect was seen. On the other hand, when buccal NTG was given 3 times a day with a 9-hour washout period, treadmill exercise time was prolonged for a period of 5 hours after a single dose. The response during therapy with transmucosal NTG was similar during the short- and long-term phases of this study. Recent studies from Germany suggest that single daily doses of sustained-release oral ISDN are not associated with tolerance, whereas more frequent dosing is associated with marked diminution of the antianginal effects.[18]

At the present time, it appears desirable to prescribe oral nitrates on a 3-times-a-day basis, with no medication after the supper dose. With transdermal preparations, one could postulate that it would be best to remove the patches after 12 to 16 hours of application to allow overnight washout.

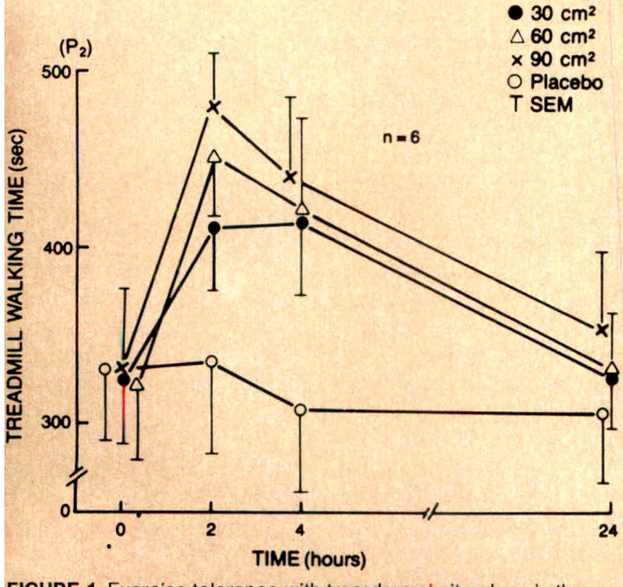

FIGURE 1. Exercise tolerance with transdermal nitroglycerin therapy (acute). Reproduced with permission from Am J Cardiol.[15]

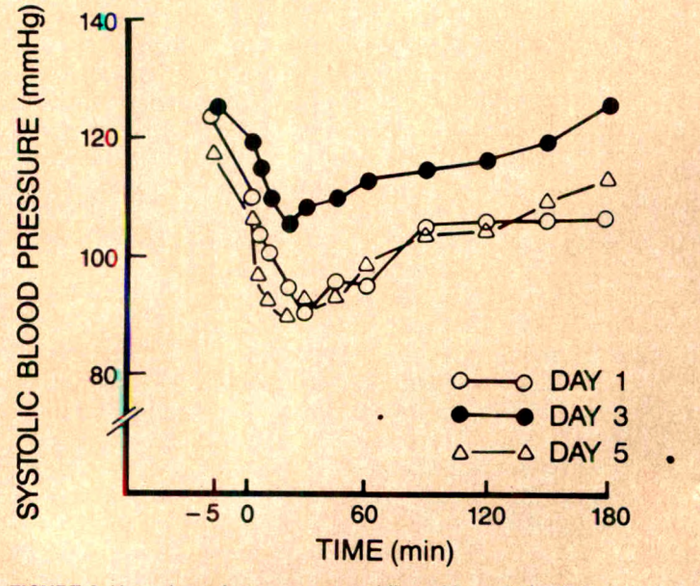

FIGURE 2. Hemodynamic response to sublingual isosorbide dinitrate challenge. Reproduced with permission from Circulation.[17]

In summary, studies have clearly documented the organic nitrates to be potent vasodilators and to induce major hemodynamic and antianginal effects. During sustained therapy with oral ISDN, transdermal ISDN and transdermal NTG, the hemodynamic and antianginal effects are attenuated. Nitrate tolerance has been shown to develop promptly but can be reversed during short periods of nitrate withdrawal. Intermittent low-dose nitrate therapy is suggested to produce prolonged clinical effects without development of clinically relevant tolerance to the hemodynamic and antianginal effects.

Hemodynamic Attenuation and the Nitrate-Free Interval: Alternative Dosing Strategies for Transdermal Nitroglycerin

JOHN T. FLAHERTY, MD

Various dosing strategies to determine therapeutic effects of nitroglycerin (NTG) preparations are reviewed. The importance of individual patient titration in establishing an effective NTG dosage is emphasized by reviewing a nitroglycerin ointment study and a crossover study. Studies reporting the development of hemodynamic attenuation ("tolerance") with long-term nitrate therapy are also discussed. The results of these and other studies suggest that the magnitude of the hemodynamic response to NTG or isosorbide dinitrate diminishes over time, with acute or first-dose effects far exceeding those obtained during long-term therapy. However, patients on long-term therapy continue to respond to sublingual NTG, which suggests that this phenomenon is not true NTG tolerance.

The effect of a nitrate-free interval as a mechanism for avoiding hemodynamic attenuation of NTG therapy is reviewed. The results of 4 studies discussed found that intermittent nitrate protocols were not associated with the attenuated hemodynamic effect observed during chronic therapy. Two possible mechanisms for the vasodilatory effects of nitroglycerin are discussed. The first relates to the production of cyclic guanosine monophosphate in the smooth muscle cells of arteries and veins; the second to the synthesis of prostaglandin I_2 by vascular endothelial cells. A mechanism by which nitrate receptors could be manipulated to increase vascular responsiveness is theorized, as well as a means by which a nitrate-free interval might avoid the development of hemodynamic attenuation in terms of cellular mechanisms and receptors.

(Am J Cardiol 1985;56:32I–37I)

Long-acting nitrates have been a mainstay in the prophylactic therapy of stable angina pectoris for the past 20 years. They can be administered orally, transmucosally or transcutaneously. Oral preparations are administered every 6 to 12 hours in order to obtain 24-hour prophylaxis. Transmucosal preparations are inserted into the buccal space every 4 to 5 hours only during the patient's waking hours to avoid the possibility of aspiration during sleep. Transcutaneous delivery of nitroglycerin (NTG) can be accomplished by application of 2% NTG ointment every 4 to 6 hours. More recently, transdermal delivery systems have been developed that deliver NTG continuously for 24 hours. Two recently published clinical studies have raised considerable controversy regarding the efficacy of long-acting nitrates, in general, and the new transdermal delivery systems, in particular.

This article will (1) present data that emphasize the importance of dose titration in individual patients, including those from our own recent study of the crossover from intravenous to transdermal nitroglycerin in patients with unstable angina, (2) review briefly several major studies on the development of hemodynamic attenuation (tolerance) during long-term nitrate therapy, (3) review 4 recent studies on the avoidance of hemodynamic attenuation by means of a dosing strategy using a nitrate-free interval, (4) discuss the cellular mechanism of NTG's vasodilating action, (5) discuss evidence for a nitrate receptor and (6) speculate on the mechanism by which a nitrate-free interval might avoid the development of hemodynamic attenuation in terms of these cellular mechanisms and vascular receptors.

Individual Dose Titration

NTG ointment was shown by Reichek et al[1] to result in a significant decrease in systolic arterial pressure, a significant increase in heart rate and a significant increase in exercise duration, 1 and 3 hours after short-term application. After 2 to 3 months of therapy, significant hemodynamic and antiischemic effects could still be demonstrated. In this study, each patient was individually titrated to ensure that an adequate hemodynamic effect was being obtained. The endpoint was a 10% lowering of systolic arterial pressure. A range of doses between 1.5 and 19.6 mg was required to obtain this endpoint in individual patients. This wide range

of doses required to obtain a significant hemodynamic effect emphasizes the limitations inherent in studies that use only a single fixed dose of a vasodilator medication in all patients.

We recently completed a crossover study (from intravenous to transdermal NTG) in patients with unstable angina.[2] This study demonstrated the importance of dose titration in individual patients for both the intravenous and the transdermal routes of administration. Seventeen consecutive patients with unstable angina were treated with intravenous NTG, which was added to any prior calcium or β-blocker therapy. Fifteen of the 17 patients became pain free. Of these 15, 10 patients had catheterization-proven ischemic etiology for their chest pain and no change in other vasoactive medications during crossover from intravenous to transdermal nitroglycerin. All 10 of these patients remained pain free during the first 24 hours after crossover. Seven of 10 remained pain free until hospital discharge. Two patients had a single episode of chest pain after temporary discontinuation or reduction of their transdermal dose. Both became pain free after restarting or restoring their original post-crossover dose. The remaining patient became unstable again, failed to respond to reinstitution of intravenous NTG and underwent urgent coronary bypass surgery.

The crossover protocol was initiated by reducing the infusion rate by 50% and applying a 5 or 10 mg/24 hour transdermal patch. After 30 minutes of observation, if the systolic blood pressure increased by <10%, then the infusion rate was decreased further. If the systolic blood pressure increased by >10%, then another transdermal patch was applied. This sequence was repeated until the infusion was completely turned off. If an episode of chest pain at rest occurred after crossover to transdermal therapy, then an additional 10 mg/24 hour patch was applied.

Five to 40 mg/24 hours of transdermal NTG therapy was required to cross over patients receiving 10 to 200 μg/min of intravenous NTG. Although we have not ruled out the possibility of spontaneous improvement, these results do suggest that crossover to transdermal NTG patches successfully maintains the beneficial antiischemic effects initially obtained with intravenous NTG therapy. These results, like the results of Reichek's study of NTG ointment, further emphasize the need for individual patient titration to establish an effective dose and, in addition, emphasize the wide range and relatively large dose of transdermal NTG required to prevent episodes of pain at rest in patients with unstable angina.

Development of Attenuation or Tolerance

Orally administered isosorbide dinitrate (ISDN) has been shown to increase treadmill exercise duration, decrease systolic blood pressure and increase heart rate in a dose-dependent fashion from 1 to 8 hours after short-term administration.[3] This same study also demonstrated significant attenuation in the systolic blood pressure lowering after 2 weeks of administration of 15 mg of ISDN 4 times a day. In this phase of nitrate therapy, a significant increase in exercise duration was demonstrable only 1 and 2 hours after administration of 15- to 120-mg doses. Attenuation of hemodynamic effects, rather than true nitroglycerin tolerance, may be a preferable term, because in most patients, the authors of this study were describing attenuation of long-term compared with short-term hemodynamic effects.

In order for the definition of true nitrate tolerance to be satisfied, it is also necessary to demonstrate loss of the ability of sublingually administered NTG to increase exercise duration during long-term NTG or ISDN therapy. Such a study was performed by Dalal et al[4] using short- and long-term administration of 30 mg of ISDN. They demonstrated a significant increase in exercise duration 2 hours after a dose of ISDN in the short-term phase of the study. However, 1 week later, after patients had received 30 mg of ISDN 4 times a day, the same dosage resulted in only half of the initial increase in exercise duration previously noted with short-term administration. Sublingual NTG failed to increase exercise duration at a time when significant hemodynamic and antiischemic effects were present. In contrast, 6 hours after an oral dose of ISDN, a time when the antiischemic effects were attenuated, the response to sublingual NTG was intact. This would suggest that patients were not truly tolerant to NTG but only needed a higher NTG blood level for the same antiischemic effect to be obtained.

Leier et al[5] have also showed hemodynamic attenuation in patients receiving oral ISDN therapy for chronic congestive heart failure. They reported significant reductions in pulmonary capillary wedge pressure, mean arterial pressure and pulmonary vascular resistance during the short-term phase and also after 3 months of therapy with 40 mg of ISDN 4 times a day. Attenuation of the arterial pressure-lowering effects was noted during long-term therapy. However, the pulmonary capillary wedge pressure- and pulmonary vascular resistance-lowering effects persisted. Measurements made during exercise revealed that pulmonary capillary wedge pressure, mean pulmonary artery pressure and pulmonary vascular resistance were lowered during both short- and long-term administration of ISDN. Persistence of the preload lowering effects would suggest that the venodilating effects both at rest and during exercise did not attenuate but in fact became even more significant, as evidenced by progressive improvement in exercise duration during the 3 months of long-term administration.

In summary, the results of these studies suggest that the magnitude of the hemodynamic response to nitroglycerin or ISDN diminishes with time; the acute, or first, dose effects far exceed those obtained during long-term therapy. On the other hand, the response of these patients to sublingual NTG persists, suggesting that true NTG tolerance had not developed. In contrast to effects on arterial pressure and systemic vascular resistance, which appear to attenuate markedly, effects on pulmonary capillary wedge pressure and pulmonary vascular resistance appear to persist without attenuation into the long-term phase of therapy.

This may well explain the persistent beneficial effects on exercise tolerance in angina and heart failure patients noted by Reichek,[1] Leier[5] and their co-workers, respectively. Other possible mechanisms responsible for NTG's persistent beneficial effects include dilation of intercoronary collateral channels and prevention of coronary vasospasm. These latter mechanisms of action, like the venodilatory actions, may also persist during long-term therapy and thereby explain the continued clinical benefit observed.

After the development of convenient 24-hour transdermal NTG delivery systems, a new wave of studies was carried out to test the efficacy of NTG therapy in angina pectoris and the clinical importance of hemodynamic attenuation. There seems to be no question that the transdermal delivery systems deliver NTG uniformly over 24 hours, much like an intravenous infusion.[6] NTG blood levels can be shown to be directly related to area of skin used for drug delivery. Beneficial hemodynamic effects appeared to be maintained for at least 10 hours after patch application, with some attenuation evident after 24 hours. Venous plasma concentrations using dosages of 5 to 20 mg/24 hours were low, however, compared with blood levels noted previously after 1.6-mg sublingual doses of NTG or 12-mg doses of 2% NTG ointment.[7] Several early clinical studies suggested that long-term beneficial effects could be obtained using relatively small doses in patients with chronic stable angina[8–11] and in patients with chronic congestive heart failure.[12,13]

In contrast, 2 recently published clinical studies raised significant doubts as to the long-term beneficial effects of transdermal NTG in delivery systems and, likewise, the 24-hour duration of action after a single-dose application. Parker and Fung[14] studied the acute effects of doses of transdermal NTG ranging from 15 to 45 mg/24 hours. They found no significant effects on exercise duration at 24 hours after patch doses of 15 or 30 mg/24 hours. Only at a dosage of 45 mg/24 hours were significant antiischemic effects still present 24 hours after patch application. Reichek et al,[15] using a mean transdermal NTG dosage of 25 mg/24 hours in the presence of concomitant therapy with β blockers or calcium-channel blockers in most patients, found significant antianginal effects after 4 and 8 hours, but were unable to find any significant antiischemic effects 24 hours after patch application.

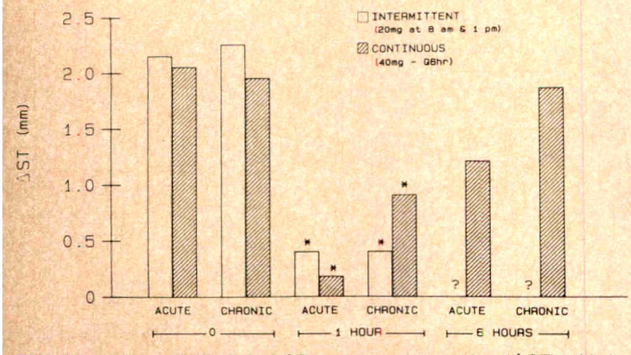

FIGURE 1. Exercise-induced ST-segment depression (ΔST) with intermittent compared with continuous oral isosorbide dinitrate (ISDN) therapy before (time 0) and 1 and 6 hours after dosing. Intermittent therapy consisted of 20 mg of ISDN administered at 8 A.M. and 1 P.M., while continuous therapy consisted of 40 mg of ISDN every 6 hours. Adapted from Rudolph.[17]

In summary, NTG tolerance, or more properly, hemodynamic attenuation, develops with all forms of NTG and ISDN preparations. Attenuation of the arterial dilating effects appears to be more marked than attenuation of the venodilating effects. It remains uncertain whether antianginal effects will follow the venodilating effects. It also remains to be demonstrated whether significant attenuation develops with the direct coronary artery dilating, intercoronary collateral channel dilating or vasospasm-preventing effects. Long-term administration of ISDN to patients with congestive heart failure results in improved exercise tolerance during long-term therapy. Therefore, at least in that patient population, clinical efficacy would appear to follow the persistent venodilating, or preload lowering, effects.

Several investigators have questioned whether continous delivery of NTG, especially at relatively small doses, may actually *promote* the development of hemodynamic attenuation. The quantity of drug delivered could be increased by using larger surface areas of skin (i.e., larger doses). Likewise, "flux enhancers" could be used to facilitate transfer of drug through the skin. It might be possible to prolong the action of the drug by slowing its metabolism. Lastly, the drug action might be potentiated by increasing the number or efficiency of drug binding sites (vide infra). Whether or not increased drug delivery alone will overcome the attenuation of hemodynamic effects noted during long-term nitrate therapy remains controversial and is one of the major goals of an ongoing multicenter trial sponsored by all 3 patch manufacturers. On the other hand, Jansen et al[16] have suggested that larger doses may in fact *increase* the development of hemodynamic attenuation.

A Nitrate-Free Interval

Rudolph et al[17] were the first to suggest that a nitrate-free interval might provide a mechanism for avoiding the development of hemodynamic and antiischemic attenuation. They demonstrated the development of "tolerance" to both the arterial and antiischemic effects of ISDN when 40-mg doses were administered 4 times a day for 2 weeks in a double-blind, placebo-controlled, crossover study. They first tested the response to sublingual NTG, 0.8 mg, in 10 patients during the short-term phase and then again after 2 weeks of long-term administration of ISDN. Sublingual NTG resulted in an 87% decrease in exercise-induced ST depression from 1.20 to 0.15 mm ($p<0.01$), and a 53% decrease from 1.90 to 0.90 mm, ($p<0.01$) during short- and long-term administration of ISDN, respectively. Eleven patients received 40 mg of ISDN every 6 hours for 2 weeks, a regimen that would result in relatively constant ISDN blood levels, and could therefore be considered continuous therapy. These investigators noted a decrease in exercise-in-

duced ST depression from 2.05 to 0.18 mm ($p < 0.01$) 1 hour after a 40-mg dose and from 2.35 to 1.20 mm ($p < 0.01$) 6 hours after a dose during the short-term phase (Fig. 1). In contrast, after long-term administration, ST-segment depression at the same workload decreased only from 1.95 to 1.65 mm (difference not significant) 1 hour after a dose and from 2.05 to 1.85 mm (difference not significant) 6 hours after a dose. Believing that a nitrate-free interval or a smaller dose would limit the development of tolerance, Rudolph et al administered ISDN intermittently, with a dose of 20 mg given at 8 A.M. and 1 P.M., leaving a nitrate-free interval at night. They administered this intermittent therapy to 10 patients for 28 days and found no attenuation of the antiischemic effects they noted previously. In these patients receiving intermittent therapy, exercise-induced ST depression decreased from 2.15 to 0.40 mm ($p < 0.01$), and from 2.25 to 0.40 mm ($p < 0.01$) during short- and long-term therapy, respectively. Thus, for the first time, the development of hemodynamic attenuation after long-term administration of a long-acting nitrate preparation was shown to be avoided by intermittent dosing.

At the 1984 American Heart Association Meeting, 3 presentations dealt with the development of nitrate tolerance and its dependence on dosing strategy. Silber et al,[18] in a double-blind, placebo-controlled trial, compared intermittent therapy, consisting of 80 mg of oral long-acting ISDN given once a day, with continuous therapy, consisting of 80 mg of oral long-acting ISDN given 2 times a day, to determine whether intermittent therapy would prevent the development of nitrate tolerance in patients with stable angina pectoris. They measured exercise-induced ST-segment depression and also ejection fraction before and during exercise (using gated blood pool scintigraphy) on the first and fifteenth days of therapy. ST-segment depression was 0.21 ± 0.6 mm after placebo administration, compared with 0.03 ± 0.05 mm on the first day of intermittent therapy and 0.03 ± 0.6 mm on the fifteenth day of intermittent therapy (Fig. 2). Likewise, the exercise ejection fraction, which was 52 ± 8% after placebo, was 67 ± 9% on the first day and 65 ± 11% on the fifteenth day of intermittent therapy. In contrast, with continuous therapy, ST-segment depression was 0.24 ± 0.7 mm after placebo, 0.07 ± 0.07 mm on the first day and 0.13 ± 0.8 mm on the fifteenth day of continuous therapy. The ejection fraction was 52 ± 15% with placebo, 62 ± 13% on the first day of continuous therapy and decreased to 56 ± 12% on the fifteenth day of continuous therapy. Thus, after 15 days of continuous oral therapy with long-acting ISDN, both the ST-segment depression induced by exercise and the ejection fraction response to exercise were returning toward control values. Although 40 to 65% of the initial improvement remained, neither variable was significantly different from control after 2 weeks of continuous nitrate therapy.

Parker and Fung[19] also studied the role of alternative dosing strategies in the development of nitrate tolerance by comparing intermittent buccal NTG therapy with continuous ISDN therapy. This was a double-blind, placebo-controlled study. The buccal preparation was administered 3 times a day, in 3 mg doses at 7 A.M. and 12 and 5 P.M., with no drug given during the night. Since the last buccal tablet was removed at 10 P.M., this therapy could be considered intermittent. In contrast, oral ISDN was given continuously with 30-mg doses administered at 7 A.M. and 12, 5 and 11 P.M. These investigators reported exercise duration after placebo and then after the first and fifteenth days of either buccal or oral therapy.

Intermittent therapy with the buccal preparation resulted in significant increases in exercise time 1, 3 and 5 hours after drug administration on both the first and fifteenth days of therapy (Fig. 3). In contrast, continuous therapy with oral ISDN resulted in significant increases in treadmill walking times at 1, 3 and 5 hours after a dose only on the first day of therapy. On the fifteenth day, the increase in exercise time was significantly different from placebo only 1 hour after a dose. Exercise times 3 and 5 hours after a dose were not significantly different from those measured after placebo. Thus, as with the 2 previously discussed stud-

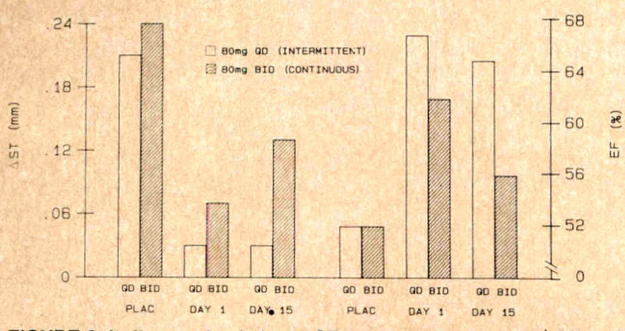

FIGURE 2. Left, exercise-induced ST-segment depression (ΔST) and **right,** ejection fraction response (%) with intermittent compared with continuous oral long-acting isosorbide dinitrate (ISDN) therapy. Intermittent therapy consisted of 80 mg of long-acting ISDN administered once daily, while continuous therapy consisted of 80 mg of long-acting ISDN administered every 12 hours. Data are presented after placebo and 1 and 15 days after institution of ISDN therapy. Adapted from Silber et al.[18]

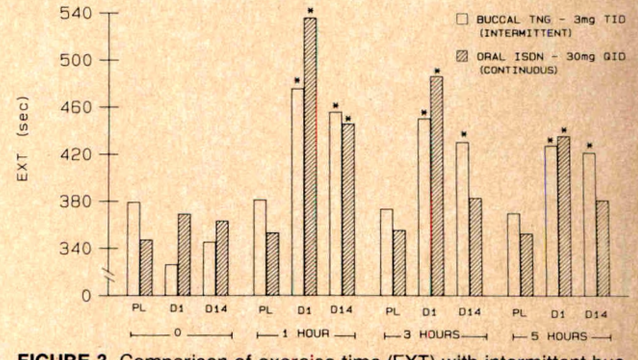

FIGURE 3. Comparison of exercise time (EXT) with intermittent buccal nitroglycerin (TNG) and with oral continuous isosorbide dinitrate (ISDN). TNG therapy was administered as 3 mg 3 times a day at 7 A.M. and 12 and 5 P.M. ISDN was administered as 30 mg 4 times a day at 7 A.M. and 12, 5 and 11 P.M. Data are reported after placebo and 1, 3 and 5 hours after dosing on day 1 and day 14 of therapy. Adapted from Parker and Fung.[19]

ies, these investigators also found that continuous therapy with oral ISDN resulted in the development of "tolerance" (attenuation of hemodynamic effects) within 15 days of initiating therapy. In contrast, when buccal NTG was administered intermittently, no significant tolerance was noted; the beneficial effects on the fifteenth day matched those observed initially on the first day of therapy.

Lastly, Reichek et al[20] compared intermittent therapy with buccal NTG (mean dose 2.8 mg) administered every 4 to 5 hours while the patient was awake with continuous delivery of NTG accomplished by means of transdermal patches. The study was also double blind and placebo controlled. Six patients first received sublingual NTG to test their NTG responsiveness (mean dose 0.38 mg). Before any nitrate therapy, sublingual NTG resulted in a 127-second increase in exercise time; 24½ hours after a transdermal dose, a 99-second increase was noted, and after 24½ hours of buccal NTG therapy, a 116-second increase in exercise time was noted. This study compared exercise times at 0, 1, 4, 6, 10 and 24 hours for intermittent and continuous administration of NTG. Exercise time increased from a control of 271 seconds to 340 to 407 seconds with intermittent buccal therapy across the entire 24-hour period (Fig. 4). In contrast, with continuous transdermal therapy (mean dose 19.2 mg/24 hours) exercise time increased from a control of 262 seconds to 352 to 356 seconds 1 to 6 hours after patch application. However, 10 hours after patch application, exercise time had decreased to 317 seconds, and after 24 hours to 262 seconds, which was identical to the control exercise time. The exercise durations at these latter 2 time points were significantly shorter than the exercise duration noted with intermittent buccal therapy. Again, as in the study by Parker and Fung,[19] since buccal nitroglycerin was not administered during the night, a nitrate-free interval was created.

Mechanisms of Vasodilating Action of Nitroglycerin

The mechanisms of NTG's vasodilating action are thought to be related to the production of cyclic guanosine monophosphate (cGMP) in the smooth muscle cells of arteries and veins[21] or to prostaglandin I_2 synthesis by vascular endothelial cells.[22] Axelsson and Andersson[21] examined the development of tolerance to NTG's vasodilating action induced in vivo in rats. They administered 15 mg/kg of nitroglycerin by subcutaneous injection, 3 times a day for 3 consecutive days. Effects on segments of aorta were then tested in vitro, as measured by the cGMP generated. Activity of guanylate cyclase, the enzyme that regulates cGMP production, was also investigated. The relaxation response to NTG in norepinephrine-contracted aortic tissue, obtained from animals pretreated with 3 days of subcutaneous nitroglycerin, was reduced 75% compared with untreated control rats. The ability of NTG to increase cGMP production was reduced by 55%, and the activity of guanylate cyclase when stimulated by nitroprusside was also found to be reduced by 75% in aortic homegenates from nitroglycerin-pretreated animals. cGMP phosphodiesterase, an enzyme that breaks down cGMP, was also shown to have increased activity in nitroglycerin-pretreated rats. These results strongly support the role of cGMP as the primary mediator in nitroglycerin-induced vascular smooth muscle relaxation, and furthermore suggest that nitroglycerin tolerance (attenuation) could be explained by reduced rates of formation and increased rates of breakdown of cGMP.

Trimarco et al[22] studied the role of prostaglandins in the vasodilating action of NTG on the coronary vascular bed of dogs. They demonstrated that inhibition of prostaglandin synthesis by indomethacin or naproxen reduced the coronary hemodynamic response to NTG infusion. They concluded that NTG exerted both a direct effect, which was responsible for the rapid initial decrease in coronary vascular resistance that they observed and that was most likely mediated by activation of guanylate cyclase, as well as an indirect effect, which accounted for persistence of the reduction in vascular resistence and which was mediated through the release of prostaglandins from the endothelial wall.

Finally, Horowitz et al[23] described a mechanism by which nitrate receptors could be manipulated to increase vascular responsiveness to NTG administration. They studied the potentiation of the cardiovascular effects of NTG by the sulfhydryl donor N-acetyl-cysteine in patients in the catheterization laboratory. They suggested that activation of guanylate cyclase by a series of enzymatic reactions was modulated by the availability of reduced sulfhydryl groups. Cysteine had previously been demonstrated in vitro to be effective in potentiating guanylate cyclase activation by NTG. In order to determine whether the hemodynamic responsiveness of NTG might be modulated by sulfhydryl availability, dose-response curves for intravenous NTG, in terms of lowering of mean arterial pressure and pulmonary capillary wedge pressure, were obtained in 10 patients during diagnostic cardiac catheterizations. Intravenous infusion of NTG was then repeated 10 minutes after intravenous administration of 100 mg/kg of N-acetylcysteine. While N-acetylcysteine itself induced no significant hemodynamic effect, after N-acetylcysteine pretreatment, a

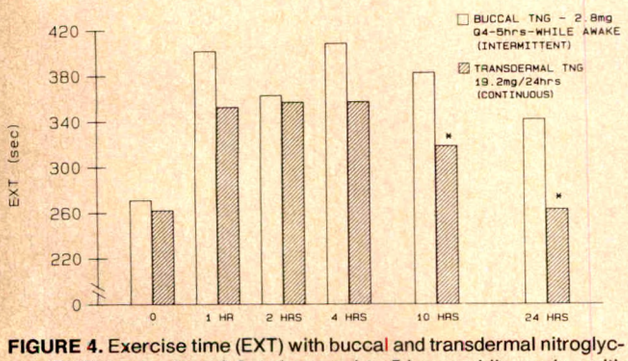

FIGURE 4. Exercise time (EXT) with buccal and transdermal nitroglycerin (TNG) (mean dose 2.8 mg) every 4 to 5 hours while awake, with continuous therapy with transdermal TNG (mean dose 19.2 mg/24 hours). Data are presented before (0) and 1, 2, 4, 10 and 24 hours after initiation of therapy. Adapted from Reichek et al.[20]

significant reduction (64%) in the NTG infusion rate was required to induce a 10% decrease in mean arterial pressure, and likewise, the infusion rate required to induce a 30% reduction in pulmonary capillary wedge pressure was also lowered by 52%. In control patients not receiving N-acetylcysteine, there was no significant difference in NTG responsiveness between 2 infusions of NTG separated by the same time interval. These investigators concluded that N-acetylcysteine potentiated the vasodilator effects of NTG in man and suggested, therefore, that sulfhydryl availability or the redux state of "NTG receptors" may be determinants of in vivo responsiveness to NTG. These data might also suggest a possible mechanism for enhancing NTG's effectiveness as a vasodilator and thereby possibly overcoming the development of NTG tolerance.

Whether the results from the studies of Axelsson and Andersson and Horowitz et al can be related to the mechanism(s) by which a nitrate-free interval avoids the development of tolerance or hemodynamic attenuation remains uncertain. We might conclude that although not structurally identified, functional nitrate receptors bind NTG, activate guanylate cyclase and thereby stimulate the generation of cGMP, which mediates vascular smooth muscle relaxation. In the presence of continuous nitrate therapy, these nitrate receptors might become oxidized, and thereby have lower affinity for NTG binding. These sulfhydryl groups could be restored to their reduced form and thereby NTG responsiveness also restored, either by removal of NTG from the receptor or by exogenous administration of a sulfhydryl donor, such as cysteine. A nitrate-free interval, by allowing blood levels of NTG to fall to near zero, might result in spontaneous release of NTG or its less active dinitrate and mononitrate metabolites from the receptors. Likewise, spontaneous reduction of oxidized receptors might also act to restore NTG's vasodilating efficacy. It is uncertain at this time what minimal duration (e.g., 1 to 12 hours) of a nitrate-free interval would be required to restore full receptor activity.

In summary, the data reviewed would suggest that clinically significant hemodynamic attenuation occurs with all forms of long-term nitrate therapy when the therapy is administered continuously. Whether hemodynamic attenuation can be overcome, and thereby the beneficial effects of nitrates in the long-term treatment of angina pectoris maintained, by higher doses administered continuously remains uncertain and awaits the results of the currently ongoing multicenter trial of transdermal NTG. It seems equally likely that a nitrate-free interval, obtained, for example, by interrupting NTG administration during the night, might provide a means of avoiding the development of nitrate tolerance. For transdermal NTG therapy, this would mean taking the patch off at bedtime and applying a new patch in the morning. For oral, buccal and ointment preparations, this could mean omitting the last dose administered at the end of the day. Whether it will be necessary to administer another vasodilator, such as a calcium-channel blocker, during this nitrate-free period to provide prophylaxis against episodes of silent or clinically apparent ischemia during the nitrate-free interval remains to be elucidated.

Discussion

Dr. Stephen Scheidt (New York, New York): This morning we heard presentations dealing with all aspects of angina and ischemia—from pathophysiology to treatments to study modalities. I would like to start this discussion by raising some issues about the basic factors involved in assessing patients with angina and developing protocols for antianginal medications. First, we have a major problem with patient selection. What kinds of patients have angina? What kinds of patients have angina in the real world? What kinds of patients have angina in tertiary care institutions? What kinds of patients have angina in studies? I don't think anyone doubts that most of the published results are true—that a certain investigator studies a certain group of patients and gets a certain result. Yet we all know from long experience that the selection of the study group has an enormous bearing on the results obtained. The ability to generalize, or lack thereof, from one group of patients to another is of enormous importance. Everybody participating in this discussion has been involved in drug trials. The patients who join drug trials are, I think, different from the general population, sometimes subtly, sometimes obviously, and I'd like to discuss, first of all, the general issue of differences between patient populations. Then, I'd like to discuss how the kinds of patients who have been studied so far may have a bearing upon the kinds of results that have been reported, particularly in the area of transdermal nitroglycerin.

The second issue, an enormous Pandora's box that has been opened by some during this symposium, is the type of angina present in the patient group selected for study. If we are to fully believe what Drs. Selwyn and Shell have told us, indeed there is really much more angina, or rather much more ischemia, in patients with coronary artery disease than we have been aware of until now. It seems, if you believe Dr. Ganz, that a very large proportion of people, at least those who are studied at the Brigham and Cedars-Sinai hospitals, have unstable angina, unstable ischemia. This question then arises: Are those patients properly represented in the studies that have been done to date with nitroglycerin or other antianginal preparations?

Furthermore, there were a number of issues that arose in Dr. Weber's presentation in terms of the diagnosis of coronary disease. Are there many false-positives in the patients who have been selected? Is it necessary to do a cardiac catheterization in everyone? Is it necessary to look for spasm in everyone? Do we need to look for platelet aggregates or activated forms of platelets in everyone? Do we need, in some way, to look at Folts'[1] types of cyclical changes in coronary flow in everyone to be sure we're studying the right group of patients? Do we need to do echocardiograms in everyone to rule out mitral valve prolapse—because otherwise we may be getting false-positive ST-segment deviations when you do Shell- or Selwyn-type Holters*? There are many questions as to how a proper group of patients with a proper and representative type of angina syndrome is selected for study.

We will want to talk about patient selection and angina selection, and then we will need to discuss test selection. Just what is the proper way to evaluate the efficacy of any antianginal preparation, particularly nitroglycerin? The Food and Drug Administration believes that one needs objective measurements, and of course one does. In this regard, exercise stress testing to submaximal levels has been chosen in the large, multicenter nitroglycerin patch trial that is currently underway. On the other hand, there are many questions as to whether that is the proper methodology for evaluating antianginal efficacy. Holter monitoring, because it's available and because many people are working with it, is another possibility, but is this the right method to use? What sort of work needs to be done in the future? Are there other aspects of study design that need to be taken into account? So, to begin, let me pose the first question to Dr. Weber. How about the question of stress testing for evaluation of angina?

Exercise Tolerance Testing for Evaluation of Antianginal Agents

Dr. Jan R. Weber (Philadelphia, Pennsylvania): Most of the studies, as you mentioned, have utilized stress testing in some way, particularly with regard to the transdermal nitroglycerin preparation. Stress testing on multiple occasions with each patient serving as his or her own control has been used as the standard method. This invariably requires that there be a period of time during which the patient is exercised repeatedly on either no medication or on a stable regimen of medications to determine a baseline level. There is also the matter of the so-called training effect. The training effect may have 2 components: actual physical training, in the sense that exercise performance is improved, and a learning factor—patients tend to learn how to walk on the treadmill over time, they become more efficient and are therefore capable of improving their exercise time, even though there are no significant changes in physiologic parameters that can be measured. So first you must establish an adequate baseline; then it's simply a matter of adding medication or adding placebo to determine whether the response changes.

Dr. Scheidt: Regarding training effect, could part of that be familiarity—less mental stress, less platelet aggregation, less coronary vasospasm? Is that conceivable, Drs. Selwyn and Shell?

Dr. Andrew Selwyn (Boston, Massachusetts): No one knows the answer to that. It is known that in a high proportion of patients with angina, you can standardize exercise tests if you take an enormous amount of trouble, as shown in John Parker's work. It is a reproducible test, but whether you use it exclusively for diagnosis or whether you extend its application for assessing treatment as well is, I think, the central point of your argument. I don't think there is any doubt that it can be standardized.

* For the purposes of this discussion, the term Holter is used to connote 24-hour ambulatory electrocardiographic monitoring. The 2 terms may appear interchangeably.

Dr. Scheidt: How many stress tests do you need for standardization? Dr. Parker, you're the expert on that.

Dr. John Parker (Kingston, Ontario, Canada): The majority of the patients that we study have had 6 or 8 tests. I think that numerous tests are necessary for standardization. It can't be done with 2 or 3 tests. Many of us who are involved in this type of research have a stable of patients, many of whom have been used in multiple studies and thus have standardized stress tests. With a new patient, I would very seldom enroll him in a study in which we are looking at the endpoint of an exercise test unless we could demonstrate that he has reproducible findings within fairly narrow ranges on 4 or 5 different exercise tests.

Dr. Scheidt: Let me immediately point out that it is rare, at least in the transdermal nitroglycerin studies, to see a randomized, double-blind exercise tolerance study that has been standardized with 4 or 5 tests. In most cases, the protocols call for 2 tests with exercise endpoint reproducibility within 10 to 20%. I don't know of any study protocols that have more than 3 tests. So this criterion would not be met in most of the published trials.

Dr. William E. Shell (Los Angeles, California): True, except with those investigators that have a history of doing long-term anginal studies, because by definition their patients have been already trained and standardized. This fact may explain the differences in results between exercise studies.

Dr. Scheidt: Absolutely.

Dr. Shell: If you take a group of patients that have been well trained, they are by definition very stable anginal patients. They can go through a washout phase without jeopardizing their health or precipitating myocardial infarction. These patients are probably a pure cohort of demand-induced angina. It is important to keep that in mind.

Dr. Scheidt: From the tone of your voice, I infer that you think that's probably not the best group of patients to use.

Dr. Shell: Actually, it depends on the agent you're studying. If you're looking at an agent whose major effect is on demand, for example, β blockers that reduce heart rate at any workload, then it may be the ideal study approach. But if you're looking at an agent whose major effect is on the dynamic nature of coronary tone, it may not be the right test. So I think it depends on the agent and on the circumstances. I think exercise testing is a very valuable way of assessing demand-induced angina. The question is whether that's the way to study all antianginal agents and all antiischemic agents.

Dr. Weber: I agree. I think we still have to look at the issue of whether exercise testing is really the appropriate way of assessing the efficacy of these medications. This question hasn't been totally resolved, at least not in my mind. Perhaps much of the data we hope to see from Drs. Shell and Selwyn with regard to Holter monitoring will be useful to us in clarifying the situation. I don't know yet which is the correct method, but I still have some doubts as to whether exercise testing per se is really the appropriate way of assessing these medications.

Dr. William H. Frishman (Bronx, New York): I would like to pose the question somewhat differently. Should a drug that has proven antianginal efficacy, that is, has been shown to reduce the frequency and severity of angina attacks, but which for some reason cannot be shown to improve exercise tolerance, still be available to physicians in practice?

Dr. Weber: I definitely think so, because under those circumstances you are really evaluating 2 different things. One is the ability to produce angina. We know that any person put on a treadmill has a limit. Whether you have coronary occlusive disease or not, everybody tires for one reason or another after a period of time. That's the way that treadmill testing was designed. So if a patient has underlying coronary occlusive disease, it comes as no surprise that regardless of medications, patients will invariably be pushed to the point where angina occurs. But that's really not what happens in their daily living situation. When people are going about their life's work, it's most uncommon for people to try to push themselves to the maximum. So when the angina threshold in these individuals is not exceeded and angina is reduced clinically during their activities of daily living, I think that that is a reasonable endpoint and reasonable goal of antianginal therapy. I don't think that anybody expects all of our patients to be totally free of angina for the rest of their lives once we get them on the ideal medication regimen.

> ***". . . I still have some doubts as to whether exercise testing per se is really the appropriate way of assessing antianginal medications."***
>
> ***—JAN R. WEBER***

Dr. Frishman: Because the FDA still mandates that an antianginal compound be shown to improve exercise tolerance before approval, and I just want to reiterate how difficult it is sometimes to show improvements in exercise tolerance owing to all the variables. One day a patient may go 5 minutes further, and on another day on the same dose go 1 minute further, while at both times the antianginal effects of the drug are consistent.

Dr. Weber: Yes, and it happens not only in cardiac patients, but those of us who are runners know that one day when you go out for a jog through the park, you will feel exquisitely good and have very good times, and the next day you'll run very slowly and feel like a slug, even though there's really nothing that you can put your finger on that's been particularly altered. This clearly happens with patients in the exercise types of protocols that have been designed.

Dr. Shell: I think we have to begin designing trials that are more analogous to the way practicing physicians are using the antianginal agents. It's really not a question of whether nitrates extend exercise tolerance in somebody with mild angina when used as monotherapy. The question is: How does one change the incidence, duration and magnitude of ischemic events in patients with various kinds of disease?

Characterization of Ischemic Disease

Dr. Scheidt: Would anybody care to estimate the incidence of supply- versus demand-induced angina? After all, what we really want is results that can be generalized to the real world and to the general population with angina. That may not be possible. It may be necessary to subdivide patients in the real world, but until now, there's been relatively

little of that. A patient with angina is any patient with angina, unless he clearly has unstable or Prinzmetal's angina. Most patients are handled as some unknown mixture. Most of them do have atherosclerotic disease, so there is an element of a demand problem. We would probably all agree that there may be some element of coronary vasospasm as well. But would you care to give an opinion as to whether there is a great deal more in the way of supply problems in the general angina population than we have heretofore been considering and that our current studies are designed to look for?

Dr. Selwyn: I don't think we have any idea at the present time. To categorize patients with angina into purely 1 group or another seems to have no basis in fact or in usefulness. If you take all of the patients with consistently reproducible positive exercise tests that we have studied, over 90% of those that you might like to call purely demand-induced angina are having asymptomatic ischemic events and symptomatic out-of-hospital ischemia without any apparent increase in demand at all. So, as far as we are concerned, the general characteristic of the disease is that of ischemia under mixed circumstances, and it is exceptionally rare to find the Prinzmetal's angina patient with normal coronaries at one end of the range or the purely exercise-induced angina patient at the other end.

When we started looking into the area of silent ischemia, we found that the majority, rather than the minority, of people that we monitor have asymptomatic ischemic characteristics on Holter tapes out of hospital. If you look at the ischemic events, Holters are probably much more objective than the patient's reported symptoms. But the fact is that they still can't tell you what events are taking place in the proximal epicardial coronary arteries. Holters cannot measure what catecholamines have done to the myocardium apart from the effect on heart rate. They don't include information about tension development at the same heart rate, which might alter as well. In other words, the factors that contribute to increased demand are many and the increases necessary to cause ischemia can be very subtle, perhaps an increase of 5 or 7 beats/min, so demand may fluctuate without detection. The question of coronary tone is even more difficult to identify. The point is that at the present there are 2 objective ways—exercise testing and Holter monitoring—of looking at the activity of the disease and these are mutually inclusive.

Dr. Scheidt: Now I'm a little puzzled. Five or 6 years ago, when Maseri's group burst on the scene with the various descriptions of spasm, a number of studies were done evaluating gross vasospasm. The one that comes to mind is the ergonovine study by Bertrand[2] in Toronto. In this study, I believe that patients who clinically only had exercise-induced angina had about a 5% incidence of positive ergonovine tests, and patients with almost exclusively angina at rest had about a 40% incidence of gross vasospasm at catheterization. Patients with rest and exercise angina had about a 15% incidence of vasospasm. This is much less than a majority. Yet you and Dr. Shell, and the several other investigators that you both cited, show much more than the majority of patients with some sort of asymptomatic, nondemand-related ischemia. How do you put that together?

Dr. Selwyn: You have just made 2 assumptions. First, that nondemand-induced angina is the result of coronary vasospasm, and second, that a positive response to ergonovine has something to do with the real activity of the disease that affects people out of hospital.

Dr. Scheidt: All right. If it is not because of vasospasm, is it because of platelet aggregates, or is it because erogonovine has a great many false-negatives?

Dr. Selwyn: No, I think we have to say at the present time that we don't know. It is food for research. Currently, the detailed sequence of mechanisms that affect each patient at any 1 time in their disease cannot be dissected out. Of course, we do have some general ideas regarding the pathophysiology of the disease. For example, we know that the majority of patients who present with angina, positive exercise tests and angiographic stenoses have those stenoses underestimated at coronary arteriography. The reduction in cross-sectional area is probably greater than we think. The second thing we know is that the majority of these people will have a great enough reduction in cross-sectional area to produce a pressure gradient, so that the poststenotic pressure is decreased, very often to the level that the subendocardium becomes pressure driven and is therefore jeopardized. And the third thing we know is that superimposed on that particular narrowing the vessel is capable of constricting and relaxing. So there you have the set-up with 2 or 3 reasons why supply might be badly upset during an ischemic episode. Moreover, there's a lot of basic research that is perhaps more convincing than the clinical work. This research suggests that when atherosclerotic lesions have very active cellular content and various growth factors and hormones are secreted locally, these vessels can have an abnormal increase in tone. My colleague, Peter Ganz, has done wonderful work in our catheterization lab showing that the endothelial-dependent relaxation of these vessels in humans is destroyed. So there is evidence of endothelial instability. All of these mechanisms are possible contributory factors and may be present in variable proportion, but you can't dissect them out in an individual using current types of monitoring.

Symptomatic Versus Asymptomatic Disease

Dr. Parker: I would like to ask either Dr. Shell or Dr. Selwyn if there is any relation between silent ischemia and the severity of angina? Do patients develop it in 1 minute on the treadmill? Ten minutes?

Dr. Selwyn: The relation to the treadmill is interesting. In the 2,000 episodes we looked at in London and the 1,000 in Boston, there is no difference in the characteristics between the painful and the painless episodes. They're just as severe, just as prolonged, and they have the same heart rate distribution a minute before. We couldn't find any convincing difference. There were minor differences, with very big overlap. We concluded that there doesn't appear to be any great difference in the characteristics between symptomatic and asymptomatic ischemia. Now in the exercise test, there is a difference. Steven Campbell, who is a cardiologist now working with us, has looked at our last 40 patients. He has found a very strong relation between the levels of positive response on the exercise test and the amount of ischemia occurring out of hospital. It appears to be, with overlap again, that patients with positive exercise tests at low workloads have more ischemia out of hospital.

Dr. Parker: In selecting patients for angina studies, we tend to have patients who will get pain within stage II or early stage III of the Bruce protocol, because once you get into 9 or 10 minutes of exercise, it's hard to show a drug effect. People just tire out. Patients who develop pain at stage II or III have fairly severe disease. Would the subset that we are selecting for our drug protocol tend to have a higher incidence of silent ischemia?

Dr. Selwyn: Yes, that's right. At stage I and II, and early stage III, they will be having anything from 4 to 15 episodes of asymptomatic ischemia a day out of hospital. At the higher stages, once they can exercise for 12 minutes, they have much fewer episodes out of hospital.

Dr. Scheidt: This is a very important point, because with the National Institutes of Health exercise protocol reported on 10 years ago by Redwood et al,[3] it was suggested that the way to select patients for angina trials is to take people who get angina between 3 and 6 minutes—this illustrates what Dr. Parker just said.

Dr. Parker: Well, that's a little different, because they were modifying the workload so that the angina would come in 6 minutes. You could have anyone from class I to class IV

Dr. Selwyn: We were using, of course, the standard Bruce protocol. But we were asking the question of why the low positive exercise test carries such a bad prognosis. And the answer appears to be, at least in Steven Campbell's work, that they are having much more ischemia out of hospital.

Dr. John T. Flaherty (Baltimore, Maryland): Dr. Shell, did I understand you to say that in your open-label trial you found a dissociation in the response of the silent ischemic episodes and the symptomatic exercise-induced episodes to transdermal nitroglycerin therapy; that the transdermal therapy worked very well for suppressing silent ischemia but not so well for suppressing symptomatic exercise-induced ischemia?

Dr. Shell: We haven't studied that systematically. I can only tell you that in patients who have exercise-induced ischemic events, it doesn't appear that we are able to abolish these events completely. People will go on having exercise-induced ischemia, and they'll take nitroglycerin for it. A study in which silent ischemic episodes are abolished and exercise testing is subsequently performed has not been done, and it badly needs to be. In addition, there are several other points to be made. Going back to Dr. Scheidt's question regarding the conditions in which nitrates are likely to work, I think that 3, 4 or 5 years from now we're going to find that nitrates in all dosage forms that provide sufficient blood levels, both transdermal and oral, are going to be useful for the treatment of these spontaneous events, whether vasospastic or demand in origin. Currently, we're just beginning to define the technology that's going to allow us to do that. My guess is that dosages will be pushed to 20, 40 and 60 mg of transdermal nitrates for exercise-induced ischemia, and there will be some effect. There'll be a 10 or 20% increase. It may disappear in 24 hours, but the incidence of these silent episodes will go down dramatically. That's my prediction. Now, is this significant? To be able to answer that, it's quite clear there are 2 pieces of information missing. First, are these silent events prognostically significant? Is there an increased incidence of these events just before a myocardial infarction? Is there a relation between the total number of ischemic events and subsequent myocardial infarction and sudden death? I think Dr. Selwyn has some preliminary data suggesting there is. Second, if you abolish silent ischemic events through treatment, do you change the relation? This is not known at the current time. But if you're planning trials that will be completed 6 months from now, a year from now or 3 years from now, you'd better have that information. Otherwise you're going to get into this dissociation problem.

Dr. Scheidt: It was mentioned here that 3 out of 80 or so patients with silent ischemic episodes have died in Jansen's[4] trial. That's a rather high number given the findings in the CASS trial,[5] for example. It's hard for me to square what you're saying—first, that there's an enormous amount of asymptomatic ischemia in the population; in fact, almost everybody with chronic stable angina has it, and second, that these episodes are important before a myocardial infarction. After all, the clinical experience of most physicians with a standard, unselected, nontertiary-care group of angina patients is that they don't die at a very great rate. So there seems to be a discrepancy.

Dr. Frishman: Well, they're treated.

Dr. Scheidt: That could well be.

Dr. Selwyn: Also, in the categorization of patients, the CASS study that you just quoted didn't even require exercise testing. Many of the patients had little or no symptoms. You have no idea if they are the patients that we've been talking about around this table. You have no idea if they have any active ischemia whatsoever. I don't think you can group patients and categorize them until you've looked at them individually with respect to symptoms, active ischemia and coronary anatomy. Those factors will tell you whether they are the type of patients that we are talking about. Dr. Parker studies people who reproducibly get ischemia on exercise. He knows physiologically who they are from his standpoint. In the CASS study, I think many of them were never exercised.

Definition of Anginal Populations

Dr. Shell: There is a critical point, though, which is the description of study groups in published reports. It's going to be important that the editors make the authors define their anginal populations. They've got to define the time to a positive exercise test response, both as a mean and standard deviation, and the number of ischemic events at baseline on Holter monitoring. John Parker's group, for example, may have no silent ischemic episodes. He may have selected a cohort of patients who have no silent ischemic episodes, but we don't know that. So I would stress the importance, at least to journal editors, of making the authors define their patient groups. How many previous exercise tests have they had, what are the training phenomena, how many silent episodes do they have? Otherwise, we're never going to sort out any of these issues. We seem to be comparing apples and oranges and grapefruit trees, and we don't know where we are.

Dr. Scheidt: Someone alluded to it earlier, but I want to raise it again. How about a patient's ability to be withdrawn from other antianginal medications? Wouldn't that also define a somewhat different group?

Dr. Selwyn: In the selection of our patients, it's a crucial first issue. If you perform Holter monitoring on usual doses of their antianginal medications, you see very few ischemic events in a large number of the patients. Once you take them off and they use nitroglycerin alone, sublingually, then the patients' responses more closely approximate their natural state. That is very common practice in clinical trials, but many practitioners are not comfortable doing that.

Dr. Shell: Not only that, but the usual washout phases are 2 weeks. This is too long. We're doing a trial with a β blocker right now, and it has a 2-week washout period. It has to be modified, because these patients probably can't go more than 48 hours without their usual antianginal medications. If they do, their frequency of both symptomatic and asymptomatic events begins to increase. They are thus at risk of developing a myocardial infarction during the washout phase.

Dr. Selwyn: We've probably studied more than 300 people over a 6- or 7-year period, and we have never had any adverse events or any troublesome side effects from taking them off drugs. We have explained to patients that they're going to get some recurrence of angina, and when they do, they should use nitroglycerin. We take other precautions as well, but we have never run into trouble doing that.

Dr. Shell: What's the duration of the washout?

Dr. Selwyn: Forty-eight hours. We would never go for a 2-week washout period.

Dr. Scheidt: Dr. Frishman, you have had a lot of experience with this. What do you think?

Dr. Frishman: Yes, we've actually done drug studies requiring drug withdrawal or washout in hundreds of patients through the years. We've had washouts as long as 4 weeks in certain studies. I must say that if you know your patients well and they are informed that they should modify their daily activity and take nitroglycerin whenever they develop chest pain, you can safely use long washout periods.

Dr. Selwyn: All of our complications, including deaths, have occurred months after the Holter monitoring when these patients were back on their usual medical therapy, often with controlled angina pectoris.

Dr. Shell: Once again, though, the point that Dr. Frishman has to understand is that if you have a group of patients that can go 4 weeks on a washout period, you have defined a certain class of patients. It would be very important for you to Holter monitor those patients at the end of the 4-week washout period to determine their incidence of silent ischemia. I would hypothesize that they probably have a very low incidence of spontaneous events.

Dr. Scheidt: So Willie Ganz's tongue-in-cheek comment—that almost everyone has unstable angina—applies to virtually everyone with a strongly positive stress test who has a lot of asymptomatic episodes on a Holter, is on multiple drug therapy and is referred to a tertiary care institution. Is that a fair assessment?

Dr. Selwyn: Moderately positive and strongly positive.

Dr. Shell: I don't use the term unstable angina, because it has certain medical-legal and treatment implications. These patients certainly have unstable ischemia, and I think that term is a fairer characterization. To me, unstable angina means progressive incidence of chest pain with electrocardiographic changes, and I think we ought to restrict the term to that.

I'll tell you 2 interesting anecdotes that will point out another problem, which is that this active phase of ischemia may have a time course to it, a factor that is going to further complicate matters. A lawyer I'm following for recurrent paroxysmal atrial tachycardia comes in and says he's no longer able to jog as far as he used to. I put him on a Holter, and he had 8 or 10 silent events with no chest pain at all—1-, 2- and 3-mm events. I put him on a treadmill and he developed 3 mm of ST-segment depression without pain. I had him catheterized and found he had a 60% proximal left anterior descending lesion with what appeared to be a luminal clot. You could see a blush, but it was not occlusive. He was then placed on transdermal nitrates, β blockade and aspirin. He was followed with Holters for 3 months, and the incidence of his ST-segment events decreased with time. Did he have a healing atherosclerotic lesion?

The second patient was a malpractice lawyer, who in January did 12 minutes on a treadmill with no problems. In February, he noticed a decrease in exercise tolerance and in April he began having episodes of chest pain. At that time, he was found to have alternating ST-segment changes on his resting electrocardiogram, and was admitted to Cedars-Sinai with a diagnosis of unstable angina. He was placed on intravenous nitroglycerin and rapidly cooled down. He was taken to the catheterization lab and found to have a 20% proximal left anterior descending lesion. There was some suggestion of a blush if you looked very closely at the films, so it was assumed that he had ruptured an atherosclerotic plaque. He was placed just on β blockade and sent home. That was on Friday. I saw him in the emergency room on Friday night and again on Saturday night. I put him on the treadmill on Monday. He developed 4 or 5 mm of ST-segment elevation on the treadmill. I put him on transdermal nitro patches in addition to β blockers, and his episodes went away. A week later he did 12 minutes on the treadmill. Then we put him on a Holter, had him stop his transdermal nitrates and within 2 hours his episodes were coming back. What's his disease, and is there a time course? He is currently on transdermal nitrates and β blockers. We'll follow him out to 6 months and then stop his medications, but it's likely that these unstable lesions have a time course. They're not the same week to week.

Dr. Scheidt: That, of course, has been known to be true with Prinzmetal's angina for some time. There are periods of activity followed by periods of inactivity.

Dr. Selwyn: Angina typically exhibits exacerbations and remissions over days, weeks and months.

Dr. Parker: That presents a problem in some of these clinical trials that are too long.

Dr. Selwyn: Yes. They remit spontaneously.

Dr. Flaherty: How do you control for the use of coronary angioplasty or bypass surgery in these populations? There seems to be an underlying assumption that these populations are going to stay untouched by invasive hands throughout this time. At our institution, patients with unstable angina are catheterized, and if the lesions look fixable, they're fixed. Are you studying only nonangioplastiable or nonoperable patients? Are you studying only patients who have too little or too much disease to qualify for surgical intervention?

> ***". . . it's a false aim to try to do any study hoping to find results that can be applied to all patients with a variable disease. I think that as long as investigators are very specific about who they've selected, time and multiple studies will tell whether the information becomes useful in the general [anginal] populations."***
>
> ***—ANDREW P. SELWYN***

Dr. Selwyn: We have exactly the same routines as you do. Most of our patients who have angina or angina equivalents and positive exercise tests have Holter monitoring before they ever come to the catheterization rooms. Then at catheterization, there is usually a diagnostic test, followed by an angioplasty 2 or 3 weeks later. That 3-week gap allows us to make other observations, clinical trials, etc.

Dr. Flaherty: Most of our hospital angioplasties are being done at the same sitting, or the next day at the latest.

Dr. Scheidt: That's all very fine for studies of Holter incidence of ST-segment deviation, but it is not fine for assembling a group of patients for a medium-term drug trial. One has to question whether the patients who are still available for drug trials are different from those of the general population.

Dr. Shell: I'm doing it differently. My position is that as long as I can control people on medical therapy, and they do not have uncontrolled angina, I can therefore follow them. I'm referring for surgery only those that I cannot control medically. So I've developed a cohort of people, up to 35 now, who have not been catheterized, but at least I'm following them long term with Holters.

Dr. Scheidt: But people who are controllable probably fall less into the category of unstable ischemia than the patients we've been talking about. There are obviously gradations here.

Dr. Selwyn: I don't think your aim should be to select a population and then generalize to the entire population of patients with ischemic disease. I think that as long as investigators are very specific about who they've selected, time and multiple studies will tell whether the information becomes useful in the general population. I think it's a false aim to try to do any study hoping to find results that can be applied to all patients with a variable disease. The populations that we and others have chosen are not unreasonable —people with chronic stable angina of different levels of severity and with different reproducibility on exercise tests —but we have carefully defined our populations. Many more studies need to be done and then perhaps we will be able to arrive at more and more general conclusions.

Dr. Scheidt: Dr. Roberts had a comment.

The Ideal Protocol

Dr. William C. Roberts† (Bethesda, Maryland): Yes. Dr. Shell mentioned journal editors in one of his remarks, and you've discussed protocol, patient and physician. I just wondered if Dr. Shell were to develop what he believed to be an ideal protocol to study anginal patients, and then he passed that protocol around to the rest of you gentlemen, how many would come to a general agreement that the protocol developed by Bill Shell was really rational and reasonable, that the number and type of patients were fair and that the physicians chosen were reasonably qualified to do that study? I realize this is a little separate from the purpose of this symposium, but it's obvious to me that there is no agreement in terms of what is ideal. Surgeons, for example, in talking about prosthetic valves, have set up very nicely what is an ideal prosthetic valve, and there's no disagreement on that. But what is an ideal protocol, agreed upon by a number of thoughtful investigators, that editors can accept and the medical community can believe?

Dr. Shell: I think the problem is not ideal protocols, because I agree with you, I don't think ideal protocols can be designed. I think the key issue is that there should be sufficient detail in the description of the study design so that people reading it can come back and reconstruct the study conditions. For example, in the Reichek study that was published in *The American Journal of Cardiology*,[6] one has a great deal of difficulty going back through it to find out who was studied. Who were those patients? How many previous exercise tests had they had? What I am asking for is more details in the method sections of clinical trials, even if they are published as an appendix or kept on file at the journal, so that when you're reading a trial there is a way of discerning who is being studied. But I don't think that you can develop an ideal protocol.

Dr. Roberts: Why can't you develop an ideal protocol? I mean, if you had your druthers, what would be your vision of an absolutely perfect protocol? It seems to me that it would be useful to have such an ideal.

Dr. Shell: We spent 2 years designing a transdermal nitroglycerin protocol for assessing silent ischemia. The problem was that we had insufficient knowledge to design the protocol. We had several questions we couldn't answer. One was this question of day-to-day ambulatory electrocardiogram tape variability; you have to build this into a study design if you're going to get appropriate numbers. Another was not knowing what kind of dosage forms to use. So I think part of the problem is insufficient knowledge of both the medications and the endpoints in the disease to design protocols appropriately. We don't know enough about the nature of the disease processes to design truly valid scientific protocols, and so there is an artificial attempt to put science into something that is in many ways an art.

Dr. Roberts: But Jan Weber was fairly critical of all these factors. I could go away from this discussion thinking it's impossible to do a good study.

Dr. Selwyn: I don't think it's impossible to define ideal goals. The reason why protocols are less than ideal, and the reason for the problems here, is that very often the research question is not sufficiently precise. The research question is frequently pretentious and attempts to generalize the efficacy of a drug for the management of a patient for life, rather than saying, can this drug favorably affect 1, 2 or 3 objective measurements, with the understanding that that's not the whole story. If you wanted the whole story, I don't think it's too hard to say that you need these drugs to control pain and active ischemia, prevent infarction and prolong life. These goals must be approached in steps.

Dr. Roberts: What if you were setting up an ideal protocol just to test the efficacy of transdermal nitroglycerin?

Dr. Selwyn: To do what? What is the research aim?

Dr. Roberts: To relieve overt chest pain, angina.

Dr. Selwyn: Looking at relief of pain has been done. And it falls short because pain is such a subjective symptom and so difficult to assess objectively.

Dr. Roberts: What would be your question, then?

Dr. Selwyn: Well, that's my own bias. We come straight back to the defense that if I passed it around the table, others might not agree, but I think that you have to use what is familiar. This would be first, the full characterization of the patient, as Dr. Shell has said, second, the standardized exercise test, because it is traditional and contains prognostic information and third, the control of all ischemia out of hospital, whether it is symptomatic or asymptomatic.

Dr. Roberts: But you've got to throw out the first 4 or 5 exercise tests before you start on that.

Dr. Shell: Or at least describe them.

Dr. Selwyn: Yes. It's difficult; we accept that.

Dr. Shell: I'd like to back up. I think we've got a fundamental problem. In acute myocardial infarction, we can agree that the endpoint is mortality rate at 1 month and 1 year. I don't think we have developed our thinking in angina pectoris to the point where we can agree on an endpoint. That's what's fundamentally stopping us in the discussion of what is an ideal protocol, or what is an ideal dosage form. I think that we need to begin evolving careful clinical subsets of patients with agreed-upon endpoints. I think John Flaherty's study is a fascinating example of a spectrum of very unstable patients who've been admitted with unstable angina, probably having multiple ischemic events, both silent and symptomatic. In contrast, there is Dr. Parker's group of patients, who are able to participate in studies over many

† Dr. Roberts is Editor-in-Chief of *The American Journal of Cardiology* and was present in the audience of the symposium.

years with extended washout phases and are probably quite stable. Until we have an assessment of those kinds of clinical subsets, and what endpoints may be useful, we cannot resolve the kinds of questions we've been discussing. I think we are going to find that to begin resolving these issues we have to develop multiple marker studies analogous to what we have in myocardial infarction. Then we will need to begin looking at relative dosages in the individual subsets. The original work done in England used 5-mg patches. It may be that that was a totally inadequate dose to deal with a very unstable group of patients. We don't know. We're just beginning to scratch the surface regarding how to do the subsetting.

Dr. Weber: I think the other thing that makes it difficult to define an ideal protocol is that the clock is moving. Five years ago, before Maseri's work in Italy, we weren't really thinking seriously about the role of coronary vasospasm in angina. Now it's a major consideration. Similarly, in recent years, Drs. Selwyn and Shell have developed techniques for completely renovating our entire concept of coronary ischemia.

Dr. Roberts: I am seeking the ideal protocol for 1985. It could change in 1987.

Dr. Shell: I agree with Dr. Selwyn. I think you are going to need to have multiple levels—complete clinical characterization, exercise tolerance, whether it's trained or untrained, as long as it is specified and you know what you're dealing with, the degree and magnitude of ischemia and the number of episodes of chest pain. In this way, the research goals of each trial can be limited. One particular phase can thus be studied, and by the time we're done—1, 3, 7 years from now—we'll be able to say, for example, that β blockade can control exercise-induced ischemia. It can't control, as a hypothesis, spontaneous ischemia. It is effective in this class of patients, but not in that class of patients. Perhaps we'll find that transdermal nitrates in trained individuals have no effect on exercise-induced ischemia, but in untrained individuals it may, or it may have a tremendous effect on spontaneous ischemia. Then, by using multiple endpoints, we can begin to give the clinician some way of quantifying his obvious impression, that, clinically, multiple agents seem to be able to control the disease we call angina pectoris. The clinician is now confused. He doesn't know what endpoint to use. He certainly doesn't use repetitive exercise testing in his office to treat chronic stable angina. I don't know of any clinicians who do that. So the FDA is imposing an endpoint that is really very far away from what the average practitioner is using to assess treated patients. Maybe the FDA is right. Maybe everybody should do an exercise test, put people on antianginal agents and then repeat the exercise test every 3 months. Medical insurance carriers would probably be horrified by that.

Dr. Roberts: Well, not only is the practicing physician confused, but the investigators can't agree, it seems to me.

Dr. Selwyn: No, I don't think there's a major disagreement. I think most people around the table agree that patients should be characterized with a great deal of detail, that the standard exercise test has value and that there is value in looking at the amount of ischemia that's going on out of hospital. All 3 of these factors should move us closer to making the ideal study.

Dr. Roberts: Okay, suppose two of you do separate studies; in 1 study, 70% of the patients with angina have systemic hypertension and 50% of them have healed myocardial infarcts, whereas in the other study only 20% of the patients have systemic hypertension and 10% have healed infarcts. Are we talking about the same group of people?

Dr. Selwyn: That's not the purpose. As Dr. Shell said, if you explain all of the patient characteristics in your methods section in the greatest detail, those people who read your article will extrapolate your findings only to that patient population when they come to practice.

Dr. Shell: One of the problems we've had is that many of the active investigators have been focused on the coronary care unit, and as Dr. Selwyn points out, have not been moving out from the coronary care unit into the real world. That's changing. I don't think the situation is nearly as hopeless as it may seem. I think that the Parker-Reichek articles have crystalized an issue on which people are beginning to focus—attenuation. There are many new criteria that now need to be evaluated. Is there attenuation of nifedipine effects? Is there attenuation with diltiazem? There may be if it's looked at in ways other than exercise testing.

> ***". . . what we need to do over the next several years is expand the work . . . to the whole spectrum of angina patients. We will want to use different endpoints and see how different drugs affect those endpoints."***
>
> ***—STEPHEN SCHEIDT***

Dr. Scheidt: Let me summarize then. I believe that although there seems to be a great deal of disagreement, there is really less than we think. What we have said, and the reason for this discussion, is that most of the data reported up to now has been using only a certain subgroup of angina patients using only a certain type of testing. What I think becomes quite clear, from both the studies that have been done and from our intuition, is that angina is not a single disease. It's not even as simple as vasospasm-versus-supply-versus-demand angina. Angina is a very complex disease syndrome. It probably varies with time in the individual patient; it varies in individual patients according to coronary anatomy and it likely varies in response to therapy. We simply have to characterize what is going on. It is highly unlikely, I think, that any single agent is going to be the best agent for angina as a global disease. Until now, most of the studies have used 1 test and presumed that the test was looking at 1 type of patient. This patient has, in general, been the type of patient who was not unstable, could perform several exercise tests over a good period of time and could have other therapies withdrawn without difficulty. I think that what we need to do over the next several years is expand the work, and certainly that is underway, to the whole spectrum of angina patients. We will want to use different endpoints and see how different drugs affect those endpoints.

Dose and Efficacy

Dr. Scheidt: Let's turn now to a question that has plagued us all: the question of dose. Will the problem of efficacy, or perhaps the problem of development of tolerance or attenuation, whatever the semantics used, be solved or at least partially obviated by changing doses? Dr. Shell, what do you think?

Dr. Shell: I think it's going to be a double-edged sword. I think we're going to uncover a new problem, that of dependence. It will be the same kind of problem that you get into with β blockers—how do you get patients off of them? I think we are going to find that there are patients who will respond to higher doses, and then you'll have a dependence problem.

Dr. Weber: On the other hand, the dependence problem doesn't negate our use of β blockers. We still use them.

Dr. Shell: It's really not a question of whether nitrates extend exercise tolerance in somebody with mild angina when used as monotherapy. The question is: How does one change the incidence, duration and magnitude of ischemic events in patients with various kinds of disease?

Dr. Scheidt: Does anybody think that responsiveness to an additional sublingual nitroglycerin for an attack of pain will be seriously compromised by standard doses, by higher doses or by the highest doses?

Dr. Parker: The data that I have mentioned suggest a normal response to all doses. There is a dose response in blood pressure and exercise tolerance from 15 to 120 mg of isosorbide dinitrate.

"It's really not a question of whether nitrates extend exercise tolerance in somebody with mild angina when used as monotherapy. The question is: How does one change the incidence, duration and magnitude of ischemic events in patients with various kinds of disease?"

—WILLIAM SHELL

Dr. Scheidt: It's been said several times, and certainly Dr. Parker has shown us data, that there really is a problem of attenuation, and it's unrelated to blood levels. On the other hand, let me be a little bit iconoclastic and point out that there are a few studies that indicate that blood levels with a single sublingual nitroglycerin dose are considerably higher than those you reach, for instance, even with substantial doses of transdermal nitroglycerin. Is it possible that there may be a blood level problem at lower doses of transdermal nitroglycerin? After all, with a sublingual nitroglycerin, you get a very rapid rise in nitroglycerin blood levels to more than 3 ng/ml, which is much higher than you get with a 5-, 10- or 15-mg patch.

Dr. Flaherty: We, too, have measured nitroglycerin blood levels, both with patches and with intravenous dosage forms. I always like to remind people that the venous blood levels that one measures are in a sense downstream from the organ of absorption. In other words, the drug, whether it's given transcutaneously or intravenously, sees central veins, arteries and capillaries before it sees the peripheral veins. In the intensive care unit where we already have central venous and arterial catheters, we can simultaneously obtain samples from the right atrium, the radial artery and a peripheral vein. With patch doses in the range of 60 to 100 cm^2 (30 to 50 mg/24 hours) we're obtaining arterial and central venous blood levels as high as 40 mg/ml, but often peripheral venous levels <1 mg/ml. These measurements would seem to confirm that the transdermal patches deliver nitroglycerin in adequate quantities. I've always had an argument with measuring peripheral venous blood levels, because we see patients who are demonstrating significant hemodynamic effects with intravenous nitroglycerin who have a peripheral venous blood level of 0. These patients must be extracting most of the nitroglycerin into pulmonary vascular and peripheral arterial smooth muscle cells and thus, there is not much to spill over into the peripheral venous circulation.

Development of Attenuation

Dr. Shell: I have a question for Dr. Parker regarding your high dose data. Have you done any trials in which you've used 1 patch, seen the development of attenuation and then placed a second patch?

Dr. Parker: The high-dose study was short term, using 1 dose. We did not use a second patch.

Dr. Shell: Because if the question is does the drug work, even your data would suggest that at the end of 24 hours, the high dose works. You raise the biologically significant work. Therefore, the drug is effective. After all, that is the relevant question. With each successive patch do you see this 24-hour effect?

Dr. Frishman: I have a couple of questions, again, going back to basic mechanisms with disulfite formation. It's been stated that if you give nitrates and tolerance develops, patients shouldn't even respond to sublingual nitroglycerin. The response to any nitrate that's given should be blunted at that point, and perhaps that whole theory of disulfite formation causing tolerance is wrong.

Dr. Parker: Unless the rapidly rising nitrate levels act to displace substrates from receptors.

"The isosorbide dinitrate data are very similar to what we see with prazosin, with the initial loss of hemodynamic effect. . . But we can overcome this problem by administering higher doses and long term we can get a sustained effect."

—WILLIAM H. FRISHMAN

Dr. Frishman: Yes. The other thing that I've seen from the blood pressure studies in which we've been involved is that when you use vasodilators, including prazosin, after the first few days of therapy, there is actually a return toward baseline, probably related to hormonal compensations. The point is, however, that although these patients return toward baseline, it doesn't mean that the effect has worn off. We can reinstate the drug's effect by giving larger doses over a period of time and obtain a sustained antihypertensive effect. The difficulty lies in a short-term study. The isosorbide dinitrate data are very similar to what we see with prazosin, with the initial loss of hemodynamic effect. The pressure doesn't go down as much because the body has

made compensations for it. But we can overcome this problem by administering higher doses and in the long term, we can get a sustained effect.

Dr. Shell: Dr. Parker, were your studies done as monotherapy, with only nitrates on board? Are there any data that assess the influence of β blockade on the development of attenuation? Because theoretically it's possible that the β blockade could attenuate the attenuation, if you will, and therefore explain some of the clinical discrepancies. After all, most patients in the real world are on β blockers plus a nitrate. If there is a discrepancy between monotherapy and acute intervention studies and clinical responses, it may be that there's an interaction between the β blocker and the nitrates to modify the attenuation that's occurring.

Dr. Parker: I am not aware of any data that specifically assess the influence of β blockers on the development of nitroglycerin attenuation. Many of the patients that Reichek studied in *The American Journal of Cardiology* article in 1984 were on β blockers. Some of them actually were on calcium antagonists, too, I believe.

Dr. Scheidt: But the number of patients was very small. Eight patients in one group, 5 in another and 6 in a third.

Dr. Parker: And that was a short-term study, too. Patients were titrated up and then exercised over 24 hours. There was no long-term data.

Dr. Shell: Do you keep diaries on these patients? Is there a positive clinical response?

Dr. Parker: I tend not to place much reliance on diaries or counts of nitroglycerin consumption. First of all, patients don't keep diaries very well. They fill them out because the doctor wants them to, but they're rarely done reliably. Secondly, having been involved in this field of research for quite some time, I have found that patients tend to modify their life-style so as not to have anginal attacks. I've seen many patients who would develop angina between 3 and 8 minutes on the treadmill, but they were experiencing very little angina in their daily lives. They've learned to modify their life-style.

Dr. Shell: But these are very stable patients who probably have, in fact, no spontaneous anginal events.

Dr. Scheidt: Both treated and untreated, patients adopt a life-style that prevents angina. Indeed there might be better ways of doing a subjective assessment than diaries. If I were to do a subjective assessment, I wouldn't use a diary of the number of nitroglycerin tablets consumed or the number of anginal episodes. I'd use a pedometer, and find out how many steps patients walked or how many stairs they climbed. I think these are the parameters that patients would adjust in relation to their exercise capacity.

Dr. Shell: I'm not arguing, I'm just trying to get a feeling for the nature of the subset we're studying.

Dr. Parker: These are patients with stable, exercise-inducible angina who don't have pain at rest and who are off all medications except sublingual nitroglycerin used in the usual fashion.

Dr. Shell: And, therefore, one couldn't use normal clinical responses as indexes of how they would respond.

Dr. Scheidt: In other words, when you showed tolerance, for instance, in the isosorbide ointment group, were the patients still "better"—however that is defined—clinically?

Dr. Shell: Exactly. After all, one of the issues that's been raised is whether an objective method like Holter monitoring is relevant to patient care. This is a legitimate question. But then I would ask this question: Is exercise tolerance testing in a patient who is not experiencing anginal chest pain a relevant endpoint? Because these patients are not experiencing anginal chest pain, and therefore what does it matter that their exercise tolerance has gone from 3 minutes to 6 minutes?

Dr. Parker: As long as you know that they are truly not having angina. Perhaps these people are not having angina because they've lowered their levels of activity.

Dr. Scheidt: Dr. Parker made a comment that he didn't follow up. I want to raise it again now. You indicated that it might be the rate of rise of drug level that's important. Any comments on that?

Dr. Parker: Just a thought, I have no data.

Dr. Flaherty: It reminds me of the calcium-channel blocker story. If a patient has calcium blockers on board, and you give a large infusion of calcium, you can overcome the "block." You're not uncovering already covered receptors, but demonstrating competitive inhibition. Likewise, it may well be that during chronic nitrate therapy there may still be more nitrate receptors that do not have nitroglycerin bound to them. If you provide an additional drug, which could bind to these receptors, more vasodilator response might still be obtainable.

Dr. Weber: I have a question for Dr. Parker. You've undoubtedly looked at Thompson's paper[7] in some detail. The results are quite disparate from yours. I'm curious as to how your methodology differed from his, or how you would account for the difference in results and conclusions?

Dr. Parker: I haven't read that paper for a long time. John, you probably are more familiar with this.

Dr. Flaherty: One thing that has always struck me about it was that he selected for chronic study the responders from his acute study. In other words, he chose the nitroglycerin responders in the acute study to sublingual nitroglycerin. Thompson determined which patients were responding to nitroglycerin patches and then enrolled these people in the chronic study. This may harken back to a comment that I made previously. If one selects from a large population of patients with stable angina, there will be a group of people who will respond to low doses of nitrates. Thompson might have been lucky enough to find that subgroup. Parker, on the other hand, might have included by chance more patients requiring higher doses of nitroglycerin to obtain a significant antiischemic effect. Anytime you study a small number of patients and remembering the 20- to 40-fold variability in nitrate responsiveness from patient to patient, you can be lucky or unlucky in your selection of patients.

Dr. Weber: To use an infectious disease analogy, I think we're trying to determine whether a medication is an effective antibiotic for the treatment of pneumonia without knowing the causative organism. In angina, there seems to be a variety of types. We have many different medications, and just because an agent doesn't work for one patient, doesn't mean it may not be applicable and perfectly effective in yet another.

Dr. Selwyn: The best analogy by far is to hypertension. It has always been obvious that once a patient develops symptomatic hypertension, it is necessary to treat the symptoms and the background hypertension. It's taken years to work out that modest levels of essential hypertension, although asymptomatic, require treatment as well. This was shown in careful prognostic studies, insurance studies and population surveys. We have the same situation with angina. Remember, in essential hypertension, progress in treatment is being made without knowing the cause of the disease. So although

we do not know the precise cause of angina in each patient, we do know a group of mechanisms against which we can target drugs.

Need for Titration and Higher Doses

Dr. Selwyn: Now, if you want to try to arrive at the best dose for the nitrate patches, it would seem to me that, with what we know, you have to carefully titrate dose against ischemia in each patient and arrive, difficult though that may be, at an ideal dose for an individual.

Dr. Frishman: That's what we're involved with in our pilot nitroglycerin study. Each patient is titrated to his or her optimal patch dose.

Dr. Selwyn: But then you have to decide whether the dose-ischemia titration is relevant if it's done on an exercise test, because we don't run exercise tests all day out of the hospital. That is another issue.

Dr. Scheidt: There are, of course, other titrations that can be used. A number of the studies up to now have been done with what is called maximal tolerated dose, which is usually to intolerable headache.

Dr. Frishman: We are frequently dosing to 200 cm^2 (multiple patches) and patients are tolerating it very well. This is in contrast to Reichek who was claiming that patients were intolerant to the drug at 40 cm^2.

Dr. Parker: One of the problems is that Reichek was testing tolerable dose in an acute situation. After 10 days of therapy, you may be able to quadruple the dose, with good tolerance.

Dr. Flaherty: The other point is that most of Reichek's patients were receiving concomitant antianginal therapy. If you've already lowered blood pressure with calcium-channel blockers or β blockers, you've got very little left to drop. This would make it much harder to demonstrate a beneficial antiischemic effect of adding nitroglycerin.

I'd like to return to the subject of titration and stress that the reason why people are not titrating is that we have a very limited availability of patch sizes. The maximum patch size available now is 30 cm^2. Given the cost of a single patch, most physicians are unwilling to submit a patient to the cost of more than 1 patch a day. Therefore, there's an upper limit, a plateau if you will, to dosing. If there were a higher range of doses available, physicians might titrate higher. Given the inexpensiveness of nitroglycerin itself and the fact that what we are really paying for is the unit in which it's packaged, it would seem to me that any dose could be developed at approximately the same price. If we could establish in some research studies the range of doses that is clinically useful, then it would seem reasonable for the manufacturers to try to cover a large range of patch sizes. Then it wouldn't be so unreasonable to prescribe a dose of 20 to 50 mg/day (40 to 100 cm^2).

Dr. Scheidt: Titration is something that is commonly done with many other types of drugs, and for reasons I don't understand, probably because you get a month at a time in a box, titration is not something that's commonly practiced with patches. We have very good reason to believe that nitroglycerin doses are highly variable from patient to patient, and I now routinely titrate. I often will start with a 5-mg patch, and very quickly, certainly by the next month's prescription, will go up to a 10-mg patch. Frequently I even go higher than that. I think that for many patients—those in our studies, in the pilot studies of Dr. Frishman and in other reported studies—the maximal tolerated dose of nitroglycerin, even relatively short term, is probably above 15 mg. I think it's 15 to 25 mg, on average, in the population.

> ***"We have very good reason to believe that nitroglycerin doses are highly variable from patient to patient. . . . There will be very few patients who will get 'optimal' effect on a 5-mg patch, which I'm sure is the most commonly used dose."***
>
> ***—STEPHEN SCHEIDT***

Dr. Selwyn: It's much higher. My patients rarely use <60 mg.

Dr. Shell: But you're a tertiary referral center, and you see the worst patients.

Dr. Selwyn: The patients we see are referred by family practitioners.

Dr. Shell: But they're still on a referral basis. You're not seeing the patients who are doing well in the practitioner's office, who are not a problem to them.

Dr. Selwyn: But the potential is there to go up to 60 or 80 mg.

Dr. Scheidt: What we all do agree on is that there will be very few patients who will get "optimal" effect, whatever that is, on a 5-mg patch, which I'm sure is the most commonly used dose in the United States today. I think we all feel that we've been using the very lowest end of clinically relevant doses. Do we all feel that patches in doses of 50 mg would be useful?

Dr. Frishman: We think even higher than that, and a much wider dose range. In fact, from 5 to 100 mg.

Dr. Flaherty: A multicenter study is currently underway with such a dose range but results are several years off. We have some limited clinical data to suggest that higher doses will be useful but we can't be 100% sure. My own crossover data would suggest the development of a 50 or a 100 cm^2 patch.

Dr. Scheidt: To sound a note of caution, we know that we don't have the data in support of doses in excess of 100 cm^2. There's the possibility that larger and larger doses will simply chase one's tail and not be useful. I don't think we know for certain at the moment. I think what we do know is that many patients will tolerate higher doses.

Dr. Flaherty: There is a common misconception that going back to nitroglycerin ointment is the solution to the problem of nitroglycerin "tolerance." I find this very difficult to understand. It seems to me that ointment or oral preparations, given 4 or 5 times a day, should provide nitroglycerin blood levels very similar to those obtained with patches left on for 24 hours. How this would solve the problem of hemodynamic attenuation baffles me.

Dr. Weber: An even more peculiar anomaly is seen in our hospital. I see the house officers applying a transdermal patch and then adding to that isosorbide dinitrate every 6

hours. These patients are getting the worst of both possibilities; they're incurring the expense of the patch and at the same time the inconvenience of taking a medication 4 times a day.

> ***"Ointment, given 4 or 5 times a day, should be very similar to a patch left on for 24 hours. How this would solve the problem of hemodynamic attenuation baffles me."***
>
> ***—JOHN T. FLAHERTY***

Dr. Scheidt: I could see that the ointment might inadvertently provide a nitrate-free interval, because the ointment levels, especially at the end of 6 hours, are low. In addition, if patients sleep 8 hours and don't get up to put the ointment on, you might again be providing a couple of nitrate-free hours.

Dr. Flaherty: One other point is that during long-term therapy, compliance is not really 100%. Patients have probably been obtaining nitrate-free intervals for years by just forgetting to take 1 dose a day of oral or transcutaneous nitrates. No one has vigorously studied this, but I suspect that nitrate-free intervals have been there all the time.

Practical Clinical Applications

Dr. Roberts: Beta blockers have been mentioned a lot here. The disease, of course, is coronary artery disease, and it's my understanding that β blockers increase the total cholesterol level by 6 to 8%. The Lipid Research Clinic studies[8] have shown that when levels are diminished by 9%, the heart attack rate goes down about 19%. The difference between a 6 to 8% increase and a 9% decrease in lipid levels is an astronomical increase in heart attack rate. It would seem that a drug like nitroglycerin, which insofar as I know does not affect cholesterol levels, would be quite beneficial.

The question I have now is what recommendations do you have for the practicing cardiologist or clinician? I mean, the discussion of all the problems is nice, but if I had angina pectoris and came in to see you, would you prescribe these patches, for example, and if so, how would they be used? In terms of the tolerance issue, it seems to be that you can skip a day or so, or even hours, and then the patches seem to be fairly efficacious. What recommendations do you have for the practicing doctor?

Dr. Shell: It depends on whether you're seeing patients on a referral basis or for the first diagnosis of angina. Those are 2 separate circumstances. Let's start with the group of patients whom I see for the first diagnosis of angina. I try to get some assessment of their left ventricular function, by looking at their electrocardiogram, by physical exam and by chest x-ray. If I have reason to believe they have not had an acute myocardial infarction, which means they have an essentially normal ejection fraction, I start them on β blockade, then see them 2 weeks later. If they are still having chest pain, I add nitroglycerin, and I frequently use the patches because of compliance issues. I then see them 2 weeks later, and if they are pain free, I repeat their Holters, because I have access to that, and then I titrate their doses appropriately. Basically, I try to abolish angina. That's in the patients with normal ejection fraction. If I have reason to believe that they have a decreased ejection fraction, then I start them on nitrates first and titrate up to a maximally effective dose, which means anywhere from 10- to 25-mg patches. Then, if I have additional problems, I tend to use a small dose of a calcium-channel blocker if their ejection fraction isn't too low.

With patients who are referred to me and are already on antianginal medication, my approach depends on the problem. At that point the usual question is whether they are candidates for mechanical intervention, either percutaneous transluminal coronary angiography or surgery. Once I've determined this, I'm left with a cohort of patients who have not had surgical intervention. Then I go through the process of modifying their antianginal agents, which are a combination, in my judgment, of β blockade, nitrates and calcium-channel blockers. First I modify the doses using chest pain as the endpoint, and then I follow it up with ambulatory monitoring. And if I have 50 patients I will wind up with about 32 different regimens, because patients are very different.

Dr. Roberts: But with what you know about tolerance right now, are you going to keep the patches on continuously or are you going to, say, skip them on Saturday and on Sunday?

Dr. Shell: I tell them to get up in the morning, take their patch off, have breakfast and shower, and put their patch back on. That gives them about an hour to an hour and a half of a nitrate-free interval. Seeing Dr. Selwyn's data, I'm not sure that's the right time. Maybe I should be telling them to take it off at night. But practically speaking, taking the patch off for a short time in the morning seems to work very well. I don't know if that's right or wrong, because I haven't exercised them, but it seems like a reasonable approach. There are some patients who've evolved their own schemes and who will use 2 patches. They'll put one on in the morning, another one on at night, and take the second one off in the morning. They've learned to titrate their own dose, and they're a very interesting group of patients.

Dr. Selwyn: I think recommendations for the use of the patch are difficult at the moment, because the whole subject is just so nascent. I think one has to tell practitioners about the patch what you tell them for other drugs—that it's generally acceptable, it doesn't have troublesome side effects and they should continue to use it if it relieves the patient's pain. But I think with regard to timing, tolerance, pulsing etc., the whole subject is just too nascent to make any definitive recommendations.

Dr. Parker: I'd like to take a crack at the question Dr. Roberts posed. I'd take an entirely different approach from that which Dr. Shell outlined. Until someone shows me in a well-controlled study that silent ischemia can be corrected, and has anything to do with prognosis, I really don't care about that. I'm treating angina. I give patients isosorbide 3 times a day and nothing after the evening meal. We don't have patches in Canada but if we did, I would have them take the patch off when they get home from work and put it on after their morning shower, giving them a 12-hour nitrate-free interval. That's the way I would handle it. We talk a lot about silent ischemia, but no one has clearly shown that it is important in terms of prognosis, or that if you treat it, it modifies the prognosis. We're going to get into the coronary artery bypass problem pretty soon, because people will start treating it without really knowing.

Dr. Selwyn: But that's already happening. When young executives in responsible jobs present who have 4 mm of ST depression in a silent positive exercise test, they are already going to angiography and being bypassed for critical lesions. There are many cardiologists, some of the most famous in this country at Cedars-Sinai, who've said that it's such a high-risk situation it warrants immediate intervention. The other thing to keep in mind is that long before the exercise test was found to have prognostic value, it was being used to assess medical therapy. Its prognostic value has only recently been demonstrated. Even now there is no evidence that if drug therapy improves exercise test measures of ischemia, this will result in improved prognosis for the patient.

". . . what recommendations do you have for the practicing cardiologist or clinician? . . . how would you suggest the patches be used?"

—WILLIAM C. ROBERTS

Ambulatory 24-Hour Electrocardiogram Monitoring

Dr. Shell: Dr. Parker's position on the need to have the validity of silent ischemia demonstrated to him is quite appropriate from a scientific point of view, but I can assure him that once he starts getting Holters and sees patients with painless episodes of 4- or 5-mm ST-segment depression followed by runs of ventricular tachycardia, he's going to modify his position a bit. It's a very frightening finding and it can quickly change your perspective. So he's quite correct. Somebody does need to do a controlled trial that proves from a scientific point of view that Holter monitoring for silent ischemia has practical value. But Dr. Selwyn's position is also correct. This technology is not difficult. The practicing community will have access to ST-segment information from ambulatory electrocardiogram tapes relatively soon. It is not difficult to do, and, therefore, we're going to run into a problem very quickly where the practicing community is going to use it, probably with inadequate information.

Dr. Scheidt: Unfortunately, I have to respectfully disagree with you. It is not easy for the practicing physician to come by such data now, because a standard Holter, as we all know, is scanned for rhythm and rhythm only. The computer systems are not to be trusted in routine use. There are some Holter services that now give you an everybeat printout, but this is exceedingly difficult to use. So unfortunately, the data are very hard to come by, and I wish I knew what to recommend.

Dr. Shell: A point that needs to be made by everyone who is speaking on this issue is that the routine Holter, i.e., arrhythmia, monitoring, as given by these computer systems, should never be trusted for assessing ischemic electrocardiographic changes. That point needs to be made consistently.

Dr. Frishman: The other problem, and I've raised this with Dr. Selwyn, is that there is still tremendous variability, both intrapatient from day to day and interpatient, with this technique. And although we all have a classic patient with a reproducible type of phenomenon, that's really more often the exception, not the rule.

Dr. Scheidt: It took, after all, about 10 years for the day-to-day variability of ventricular premature complexes on arrhythmia Holter monitoring to be fully realized.

Dr. Shell: The data for beginning to assess Holters as a prognostic indicator probably already exist in all of our data pools. Most hospitals save their Holter tapes. Someone could go back, draw out those tapes and do a forward analysis of who did and did not survive.

Dr. Selwyn: The arrhythmia tapes in most hospitals are really not calibrated. The R wave is greatly amplified for analysis, so it distorts the ST segment and you get a lot of false-positives. There are, however, 1 or 2 studies in this country involving thousands of people with calibrated Holter tapes that have not been analyzed for ST-segment changes. So a study such as you recommend could be done.

Conclusions

Dr. Scheidt: It seems that the watchword of this symposium has been variability. Variability in patient selection, variability in pathophysiology of angina and variability in protocols. Let me refer briefly to how terrible the variability problem really is in terms of the findings. When you put it all together, it's not surprising that we should have no definite answer. The first thing that jumps out at you are the numbers—the numbers of patients in all the nitroglycerin patch studies are absurdly small. The mean is 10 to 12 patients. We talked about β error before. This is an enormously important point: the potential for difference between biological significance and statistical significance. And so, for instance, you see anomalies such as Reichek's, a study commonly perceived to be negative, which actually showed a 39% increase in exercise time. This used the maximal tolerated dose of transdermal nitroglycerin, a mean of 22 mg, and total exercise time as an index of efficacy. I've taken the FDA-approved measure of efficacy here—total exercise time—though we've all agreed there may be many other measures of efficacy that are more appropriate. We see a 39% increase in exercise time versus placebo, and yet because there are only 5 patients in the group, it's not statistically significant.

The second problem that's been alluded to several times is considerable variability in concomitant therapy. In Reichek's study, the patients were on other therapy. In several other studies they were not. There is no attempt among published reports to account for the possible impact of variations in concomitant medications on study results.

The third major problem in these studies is dose. In most cases, the doses used are rather small. This is true in both short- and long-term studies. If there is tolerance and such a low dose is then tested, I think it's not surprising to find a very small effect.

Some of the studies seem to be negative, and yet they show increases versus isosorbide. They show less in the way of ST-segment depression on 24-hour ambulatory electrocardiogram monitoring. With all the confusion that there seems to be then regarding variability in results, there are certainly a number of studies that show significant increases in exercise time early in treatment, and with somewhat more difficulty, show it later.

To sum up then, I think that objective efficacy in increasing exercise time is demonstrated frequently, and certainly in short-term studies. Efficacy is easy to show in the first 2 to 12 hours, and it's easy to show with larger doses. It's harder to show at 24 hours, but there are some positive trials, and interestingly, the positive trials have a reasonable number of patients. After long-term dosing, and really only long-term dosing has relevance to the clinical situation—the fact that you can show a change 4 hours after the first dose of nitro-

glycerin is interesting but unfortunately not very clinically useful—several studies show a significant increase in exercise time at both 2 to 4 and 24 to 48 hours. There are lots of scattered results that may or may not be positive depending on your bias. Again, I have put myself into the straightjacket that we have all been in up to now—using only the single parameter of exercise stress testing. And, of course, all of the studies had slightly different protocols and looked at slightly different parameters. Some did Holter monitoring and some did not.

In general, it's very difficult to draw definite conclusions. The clinical trials to date are small. Most, but not all, are randomized and blind; some, but not all, stopped other medications. Most of them used only 1 or 2 doses, and they were low doses. One of the things that's not an issue among the panel is that if you titrate transdermal nitroglycerin, every one of us is astounded at the doses we can reach. It's something I did not foresee when we started this research. Clearly there is not only great interpatient variability in the ability to receive nitroglycerin, but patients also have an enormous ability to receive nitroglycerin, so that the maximal tolerated dose has been surprisingly high. Regarding patient satisfaction and physician satisfaction, these are very soft data. We all agree on that and, I am afraid that as much as one would like to, it's difficult to find any significant way of interpreting this. We can, however, try to get a feel for what the soft data indicate. Most of the studies do keep angina counts, angina attack diaries and nitroglycerin counts, and many of them are favorable.

So there is more than a suggestion that patches are effective in certain groups of patients. I think the challenge of the next couple of years is, first, to find out if this is true in few, some or many patients. In addition, we will need to address such issues as proper dose, proper method of administration—nitrate-free interval or otherwise—and the proper endpoints to use. Should the method to assess efficacy be stress testing, should it be measurement of silent ischemia, should it be something else entirely? I think we have to conclude that we still have a great deal of work to do in this area to arrive at any definite conclusions, but hopefully we're on the way to resolving many of these problems.

CME Test 1A

Symposium on Transdermal Nitroglycerin

Cornell University Medical College designates this continuing medical education activity for 5 credit hours in Category 1 of the Physician's Recognition Award of the American Medical Association. Answers are to be marked on the sheet on page 531.

1. What percentage of episodes of myocardial ischemia on 24-hour ambulatory electrocardiographic monitoring is asymptomatic?
   a) about 10%
   b) about 25%
   c) about 50%
   d) 66 to 75%

2. Episodes of silent ischemia on ambulatory electrocardiographic monitoring have median duration measured in:
   a) seconds
   b) minutes
   c) hours
   d) none of the above

3. A large proportion of episodes of silent ischemia on ambulatory electrocardiographic monitoring occur during:
   a) heavy physical exertion
   b) modest physical exertion
   c) anxiety
   d) none of the above

4. Episodes of silent ischemia seen during ambulatory electrocardiographic monitoring tend to be most prominent:
   a) during the first 4 to 6 waking hours of the day
   b) immediately after meals
   c) in the early evening
   d) during night time hours

5. Hemodynamic events occurring at or before the onset of episodes of silent electrocardiographic ischemia almost invariably include:
   a) increases in blood pressure
   b) increases in heart rate
   c) increases in both heart rate and blood pressure
   d) none of the above

6. Drug delivery with transdermal nitroglycerin patches depends on:
   a) location of the patch
   b) characteristics of the patient's skin
   c) skin blood flow
   d) none of the above

7. Possible reasons for inconsistent results regarding efficacy of transdermal nitroglycerin patches include:
   a) small number of patients studied per trial, averaging 10 to 15 patients per study
   b) use of maximal or submaximal stress testing rather than anginal attack rate or other ambulatory measure of efficacy
   c) possible attenuation or tolerance with continuous use of nitroglycerin
   d) all of the above

8. Hemodynamic effects of organic nitrates include:
   a) direct venodilation at low plasma concentrations
   b) direct arteriolar dilation at higher plasma and tissue concentrations
   c) coronary vasodilation
   d) all of the above

9. Nitrates:
   a) decrease endothelial cell production of prostacyclin
   b) interact with sulfhydryl groups on nitrate receptors on cell membranes
   c) are excreted by the kidney
   d) all of the above

10. Oral nitrates:
    a) must be given in large doses to overwhelm hepatic first-pass enzymatic breakdown
    b) often must be administered in doses higher than recommended by manufacturers
    c) have been associated with partial tolerance
    d) all of the above

11. Transcutaneous nitroglycerin, either ointment or patches, should be administered:
    a) through the skin of the anterior chest wall or proximal aspect of the upper limbs
    b) at the same skin site day after day
    c) at relatively low dose to avoid tolerance
    d) all of the above

12. Noncardiac effects of nitroglycerin include:
    a) increased gastrointestinal motility
    b) decreased esophageal spasm
    c) pulmonary bronchoconstriction
    d) none of the above

13. Adverse effects occasionally seen with nitroglycerin include:
    a) worsening angina from reflex tachycardia
    b) increased intracranial pressure
    c) mild nausea
    d) all of the above

14. Silent myocardial infarction:
    a) occurred in 15% of middle-aged men in Framingham
    b) made up 15% of transmural myocardial infarcts in Framingham
    c) occurs more often than myocardial infarction with symptoms in middle-aged American men
    d) none of the above

15. Episodes of transient asymptomatic ST depression on ambulatory monitoring:
    a) have been associated with perfusion defects on rubidium or thallium scanning when done during the episode
    b) are often related to electrolyte abnormalities
    c) have been shown to be artifactual and related to monitoring equipment in many cases
    d) all of the above

16. In various autopsy and angiographic studies, the incidence of significant coronary artery disease in asymptomatic and presumably healthy American men is about:
    a) 0 to 2%
    b) 2 to 5%
    c) 5 to 8%
    d) 8 to 10%

17. Diminution of some of nitroglycerin's effects when administered chronically is likely to be:
    a) attenuation, not true tolerance, because responsiveness to a "bolus" or acute increase in blood level (e.g., with an additional sublingual nitroglycerin) still persists
    b) less prominent for venodilating effects than other hemodynamic effects (i.e., reduction of preload persists even with prolonged and continuous usage)
    c) overcome by titrating and increasing the dose of nitroglycerin
    d) all of the above

18. Possible strategies to overcome potential nitroglycerin attenuation or tolerance include:
    a) increase in dosage when used chronically
    b) a nitrate-free interval
    c) reliance on transdermal nitroglycerin for less than 24 hours
    d) all of the above

19. N-acetylcysteine:
    a) has no hemodynamic effect of its own
    b) potentiates activation of guanylate cyclase by nitroglycerin, perhaps by making more reduced sulfhydryl groups available
    c) enhances nitroglycerin's vasodilator effects
    d) all of the above

20. A nitrate-free interval:
    a) has been shown effective in a few small studies in restoring exercise response to various nitroglycerin preparations including continuous long-acting isosorbide and transdermal nitroglycerin
    b) may require a substitute antiischemic agent during the interval, although definitive testing of this possibility is not available
    c) may allow release of nitroglycerin from oxidized receptors, and thus spontaneous reduction of the receptors, to restore nitroglycerin responsiveness
    d) all of the above

A Symposium: Laboratory Lipid Values

Introduction

SCOTT M. GRUNDY, MD, PhD

In recent years there has been increasing interest in the role of plasma cholesterol and lipoproteins in the causation of coronary artery disease (CAD). The relation between a high level of plasma cholesterol and rates of CAD is now well established. There is also growing evidence that specific lipoproteins are involved in the atherogenic process. For instance, the low density lipoproteins (LDLs) have been identified as the most highly atherogenic of the lipoproteins. The high density lipoproteins actually may be antiatherogenic, as high levels of high density lipoproteins appear to be protective against CAD.

The relation between the plasma lipoproteins and CAD has been established mainly through epidemiologic studies. On the basis of these studies, general recommendations have been made about changes in diet and life-style that will modify the metabolism of lipoproteins and thus may protect against atherosclerosis. However, many investigators have been uncomfortable with recommendations made without proof that actual modification of lipoprotein levels will alter the risk for CAD. In recent years, several clinical trials have provided supporting evidence that "favorable" alterations in lipoprotein levels actually decrease the risk for CAD. Of particular importance was the recent Lipid Research Clinics Coronary Primary Prevention Trial. This trial demonstrated that lowering of LDL levels does decrease rates of CAD. This finding has greatly stimulated interest in prevention of CAD through alteration of cholesterol (and LDL) levels.

In the wake of this trial, the National Institutes of Health convened a Consensus Conference on Cholesterol, which resulted in the issuance of a report indicating that elevated cholesterol levels are a significant risk factor for CAD. Further, it was recommended that both physicians and the general public take steps to reduce cholesterol levels, focusing in particular on patients with elevated levels.

In light of this, several distinguished physicians, laboratory directors and biochemists were invited to address critical issues in the evaluation of patients suspected of having lipid disorders and in the interpretation of laboratory values for these individuals. Specific questions addressed by the panel included: what are lipoproteins and how should they be tested; what is the reliability of lipoprotein testing; what should be considered a normal range for plasma lipids and lipoproteins; and, finally, who should be tested and how should results be interpreted?

It is the intent of this symposium supplement to provide a discussion of the problems confronting the clinical laboratory in the accurate measuring of lipids and lipoproteins, and in the reporting of these values in a useful way to the physician.

From the Departments of Internal Medicine and Biochemistry and the Center for Human Nutrition, University of Texas Health Science Center, Dallas, Texas 75235.

Classification and Structure of Lipoproteins

ANTONIO M. GOTTO, Jr., MD, PhD

The lipoproteins were first discovered in the late 1920s by Macheboeuf who used ammonium sulfate precipitation to separate and fractionate the lipoproteins.[1] In the 1940s, they were further studied, first by Oncley and his group at Harvard, using Cohn fractionation, and later by Gofman and associates at the Donner Laboratory in California. Gofman et al[2] used analytical ultracentrifugation to separate the lipoproteins based on their rate of flotation in the ultracentrifuge. In the mid-1950s, Havel, Eder and Bragdon[3] introduced preparative ultracentrifugation, which remains the classic way of separating the plasma lipoproteins. In the 1960s, Hatch and Lees used albumin in buffer, which resulted in a much cleaner separation of the lipoproteins on paper electrophoresis. This technique was subsequently adopted by Fredrickson, Levy and Lees,[4] who used electrophoresis along with preparative ultracentrifugation and heparin manganese precipitation as the basis of a system for phenotyping the plasma lipoproteins.

The introduction of a simple system for classifying plasma lipoprotein disorders based on phenotypes helped to generate an outburst of interest in research in the plasma lipoprotein field (Table I). More recently, zonal centrifugation for dividing lipoprotein classes into subgroups and the use of monoclonal antibodies to identify apolipoproteins have been introduced.

The plasma lipoproteins are macromolecular complexes held together by noncovalent, primarily hydrophobic, forces, and serve as the carriers of lipid in plasma. With the exception of the fatty acids, which are carried by albumin, all of the plasma lipids are transported in association with plasma lipoproteins.

One of the functions of this group of particles is to serve as a detergent to solubilize and protect the water-insoluble lipids—cholesteryl esters and triglycerides—as they are carried in the blood. The major lipid components of the plasma lipoproteins are phospholipids, cholesterol, cholesteryl esters and triglycerides. Table II lists the composition of each lipoprotein class. The protein components are called apolipoproteins.

Lipoproteins appear as spherical particles, with the water-insoluble lipids at the center or core, when observed with the electron microscope. They are surrounded by a surface monolayer consisting of the apolipoproteins and the polar parts of the phospholipids. It is believed that cholesterol lies somewhere between the surface monolayer and the central core of the neutral lipid (Fig. 1). The apolipoproteins seem to contain specific lipid-binding regions called amphipathic helixes; apparently, these are the sites that serve for interaction in binding between the apolipoprotein and the phospholipid.

Five major classes of the plasma lipoproteins have been identified (Table II). The basis for their classification and separation remains the ultracentrifuge and electrophoresis. Chylomicrons are the largest of the particles, and are made in the gut. They reach the circulation by the lymphatic system and carry the dietary triglyceride and cholesterol.

The next largest particles are the very low density lipoproteins (VLDLs), which are made in the liver. They carry triglyceride and cholesterol, are synthesized within the body and serve as a major transport system for the endogenously synthesized triglycerides. On electrophoresis, VLDLs lead the beta globulins in migration; thus, they are also called the pre-β lipoproteins.

Smaller than VLDLs, the intermediate density lipoproteins are the family between VLDLs and low density lipoproteins (LDLs). It is thought that they represent intermediate stages in the conversion of VLDLs to LDLs.

The fourth group, and one of the most significant with regard to arteriosclerosis, is the LDLs. LDLs are the major cholesterol carriers in the blood, and are synthesized primarily in the liver. Their major protein constituent is apolipoprotein B. The LDLs migrate with the β globulins and are also called β lipoproteins.

The fifth family of lipoproteins is the high density lipoproteins (HDLs). They are also called α lipopro-

TABLE I Hyperlipoproteinemia Phenotype Definitions and Their Association with Genetic and Other Disorders

Phenotype	Common Name	Laboratory Definition	Associated Genetic Disorders	Conditions Associated with Secondary Hyperlipoproteinemia
Type I	Exogenous hyperlipidemia	Hyperchylomicronemia and absolute deficiency of lipoprotein lipase or postheparin lipolytic activity Cholesterol normal Triglycerides greatly increased	Familial LPL deficiency ApoC-II deficiency	Dysglobulinemia, pancreatitis, poorly controlled diabetes mellitus
Type IIa	Hypercholesterolemia	LDLs increased Cholesterol increased Triglycerides normal	Familial hypercholesterolemia LDL receptor abnormal Familial combined hyperlipidemia Polygenic hypercholesterolemia	Hypothyroidism, acute intermittent porphyria, nephrosis, idiopathic hypercalcemia, dysglobulinemia, anorexia nervosa
Type IIb	Combined hyperlipidemia	LDLs increased VLDLs increased Cholesterol increased Triglycerides increased	Familial hypercholesterolemia Familial combined hyperlipidemia	
Type III	Dysbeta-lipoproteinemia	Floating β-lipoproteins VLDL cholesterol/VLDL triglyceride >0.35 ApoE-II homozygote on isoelectric focusing Cholesterol increased Triglycerides increased	Familial dysbeta-lipoproteinemia	Diabetes mellitus, hypothyroidism, dysglobulinemia (monoclonal gammopathy)
Type IV	Endogenous hyperlipidemia	VLDLs increased Cholesterol normal or increased Triglycerides increased	Familial hypertriglyceridemia Familial combined hyperlipidemia	Glycogen storage disease, hypothyroidism, disseminated lupus erythematosus, diabetes mellitus, nephrotic syndrome, renal failure, ethanol abuse
Type V	Mixed hyperlipidemia	Chylomicrons and VLDLs increased LDLs present but reduced Cholesterol increased Triglycerides greatly increased	Familial hypertriglyceridemia Familial multiple lipoprotein-type hyperlipidemia	Poorly controlled diabetes mellitus, glycogen storage disease, hypothyroidism, nephrotic syndrome, dysglobulinemia, pregnancy, estrogen administration (either contraceptive or therapeutic) in women with familial hypertriglyceridemia

LDL = low density lipoprotein; VLDL = very low density lipoprotein.

TABLE II Chemical Composition of Normal Human Plasma Lipoproteins

	Surface Components (mol%)			Core Lipids (mol%)	
	Cholesterol*	Phospholipids	Apoproteins	Triglycerides	Cholesteryl esters
Chylomicrons	35	63	2	95	5
VLDL	43	55	2	76	24
IDL	38	60	2	78	22
LDL	42	58	0.2	19	81
HDL_2	22	75	2	18	82
HDL_3	23	72	5	16	84

* May be distributed between the surface and core and, in the case of large chylomicrons, more cholesterol may be in the core than on the surface.
HDL = high density lipoprotein; IDL = intermediate density lipoprotein; LDL = low density lipoprotein; VLDL = very low density lipoprotein.
From Smith LC, Massey JB, Sparrow JT, Gotto AM Jr, Pownall HJ. Structure and dynamics of human plasma lipoproteins. In: Pifat G, Herak JN, eds. Supramolecular Structure and Function. New York: Plenum, 1983: 213.

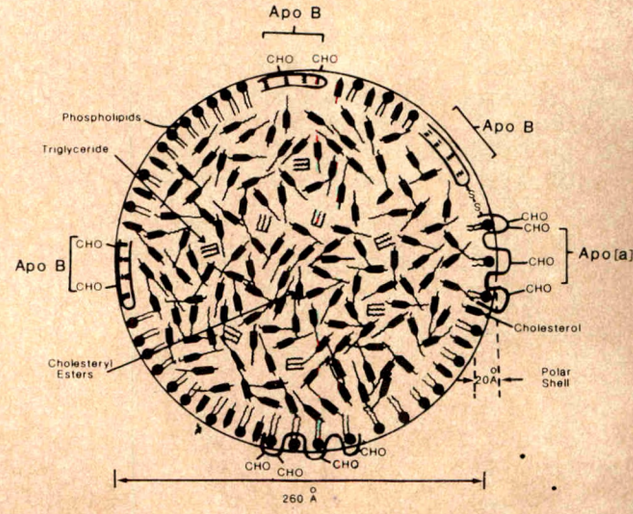

FIGURE 1. Model of lipoprotein [a] molecule illustrating the spatial relation of the neutral lipid core to the polar lipid shell. Courtesy Baylor College of Medicine.

teins because they migrate with the α globulins. The HDL family members are relatively rich in protein; they contain approximately one-half protein and one-half lipid, by weight. The major lipid constituents are phosphatidylcholine or lecithin and cholesteryl ester. They are subdivided into 2 categories, HDL_2 and HDL_3. This subdivision may be important in relating the relative protection of HDLs to coronary artery disease.

Relation of Elevated Blood Lipid Levels to Development of Atherosclerotic Plaques

WILLIAM C. ROBERTS, MD

At least 6 factors indicate that elevation of the blood cholesterol level (particularly the low density lipoprotein [LDL] component that is reflected by the plasma or serum total cholesterol) is essential for the development of arterial atherosclerotic plaques large enough to cause organ ischemia:

1. Atherosclerotic plaques in both human and nonhuman animals contain cholesterol esters;
2. Atherosclerotic plaques can be produced in certain nonhuman animals (e.g., baboons, monkeys, rabbits) by feeding these animals diets high in cholesterol and saturated fats;
3. In nonhuman animals that have developed atherosclerotic plaques as a result of being fed diets high in cholesterol and saturated fats, the atherosclerotic plaques regress when the atherogenic diet is discontinued;
4. Persons who have extremely elevated total serum cholesterol levels (>500 mg/dl), in which the dominant component is LDL cholesterol, have extensive atherosclerosis at an early age. (These persons have homozygous type II hyperlipoproteinemia.) Without effective lipid-lowering therapy, these persons usually die from consequences of severe atherosclerosis before the age of 20. In other words, when the LDL is greatly elevated, the amount of atherosclerotic plaque is extensive and develops at an early age. The greater the quantity of LDL cholesterol in the blood, the greater the quantity of atherosclerotic plaque on the arterial wall.
5. Individuals with low (<150 mg/dl) total serum cholesterol levels have no or insignificant amounts of atherosclerotic plaques. Necropsy studies of the coronary arteries, aorta and circles of Willis in populations with total serum cholesterol levels <150 mg/dl (from certain parts of Asia and Africa) have demonstrated few or no atherosclerotic plaques.
6. Lowering the blood cholesterol level, when it has been significantly elevated, has been demonstrated to lower the frequency of development of symptomatic or fatal coronary events. The Lipid Research Clinics Coronary Primary Prevention Trial has unequivocally demonstrated that when the plasma total cholesterol is lowered in persons with high levels (>265 mg/dl), the frequency of fatal and nonfatal myocardial infarction, sudden coronary death, angina pectoris, positive exercise stress test and need for coronary artery bypass surgery is reduced.[1]

Discussion

Dr. Grundy (Dallas, Texas): Dr. Gotto, could you summarize the major points that clinicians should be aware of concerning lipoproteins?

Dr. Gotto (Houston, Texas): The physician needs to know which lipoprotein families are associated with coronary disease and which are relatively protective against it. Dr. Roberts mentioned the strong evidence associating high levels of low density lipoprotein with the prevalence and severity of coronary artery disease. There is an inverse relation that is now well known and well characterized between high density lipoproteins and coronary disease.

Beyond that, I think that the physician needs to know that chylomicrons are the particles that carry the dietary triglyceride and that they may be elevated in some individuals after a fatty meal. The triglycerides that are made in the body are carried in the very low density lipoproteins. So if one eliminates chylomicrons, a measurement of triglyceride is primarily associated with the level of the very low density lipoproteins.

Dr. Grundy: Dr. Cooper, did you have a comment?

Dr. Cooper (Atlanta, Georgia): Yes. Both Drs. Gotto and Roberts mentioned the risk associated with most of the lipoproteins, but the risk associated with very low density lipoproteins, cholesterol and cholesterol remnants was not mentioned. I wonder if very low density lipoprotein and triglycerides are associated with coronary artery disease risk, through the low density lipoprotein cholesterol as well as through the increased metabolic reactions?

Dr. Gotto: Yes, I think that while triglyceride as an independent risk factor has not been definitively proven in epidemiologic studies, elevations of triglyceride are associated with other factors and metabolic problems that we know are themselves associated with an increased risk of coronary disease. There is also a statistically reciprocal relation between triglycerides and high density lipoprotein. The higher the triglyceride factor, the relatively lower the concentration of high density lipoprotein. It is possible to factor out triglycerides in a multifactorial analysis, but it does not necessarily mean a high level is safe. But the risk of triglycerides is probably related to other metabolic problems, which themselves predispose a person to increased risk of coronary disease progression.

Dr. LaRosa (Washington, D.C.): We have to consider when intervention is necessary in patients whose cholesterol levels are elevated. We have known for some time that there are early lesions in adolescents and in young adults that do not have the same complexity as arteriosclerotic lesions in older people do. Can you tell us whether those lesions do, in fact, progress? Does the presence of lesions provide us with any guidance about whether or not we should be considering intervention in young adults?

Dr. Roberts (Bethesda, Maryland): We have found lipid lesions in teenagers and adults in central Africa. These teenagers had very low cholesterol levels, generally about 100 or 110 mg/dl. In the United States, the occurrence of lipid lesions in teenagers is relatively common. These lipid lesions do not progress to fibrous or complicated plaques in the population groups where the total cholesterol levels are 110 or 120 or certainly under 150 mg/dl. In most people in this country, fibrous lesions begin developing in coronary arteries during adolescence, whereas they do not in those populations where the lipid levels are low. I am not convinced, however, that these minor lipid lesions are really precursors of the plaques that become large enough to narrow arteries.

It is important to realize that atherosclerosis is an intimal lesion and that these early plaques contain a great deal of lipid. On the other hand, in the person aged 70 who has a fatal acute myocardial infarction or sudden coronary death, the dominant component of the arteriosclerotic plaque is not lipid, but collagen.

Dr. Grundy: Dr. Gotto, you have already identified low density lipoprotein as the major atherogenic lipoprotein. We know of the exciting finding that most of the low density lipoprotein is removed from the circulation by receptors on the surface of cells. What role do you think these receptors play in the development of arteriosclerosis or in the overall causation of high cholesterol levels?

Dr. Gotto: I think that the low density lipoprotein receptor or the specific low density lipoprotein receptor as it was first discovered by Brown and Goldstein[1] plays primarily a protective role by lowering the level of low density lipoprotein and low density lipoprotein cholesterol circulating in the blood. There is a nonspecific pathway, in which cholesterol and low density lipoprotein are removed, but probably one-half to two-thirds of the low density lipoprotein and low density lipoprotein cholesterol are removed via the specific pathway. This receptor may be affected by diet, drugs and various factors that alter the intracellular level of cholesterol.

For example, one lipid-lowering agent pulls out the bile acids from the intestine into the stool. By lowering the level of bile acids, the level of cholesterol decreases within the cell, within the liver. The cell responds to this decrease in intracellular cholesterol, we believe, by making more receptors, and as it makes more receptors, the liver is able to pull more low density lipoprotein out of the blood. So, the type of diets or types of medications that decrease the level of cholesterol within the liver would be expected to increase in the activity of the low density lipoprotein receptor, and decrease the concentration of low density lipoprotein. Then, based on the cholesterol or lipid hypothesis, as stated by Dr. Roberts, this would decrease the risk of cholesterol and low density lipoprotein deposition in arteries.

Reliability of Lipid and Lipoprotein Testing (I)

HERBERT K. NAITO, PhD

The accuracy and precision (within-day and day-to-day reproducibility) of lipid and lipoprotein tests must be considered in addressing the question of reliability. Most analytical variance is classified as either systematic or random. Systematic variance includes variations that influence observations consistently in one direction or another. Systematic variance may arise from either natural or man-made events of which the investigator may or may not be aware. The sources of systematic variance are aging, personal bias of the analyst, laboratory bias, inter- and intraindividual bias and experimental error.

Random variance includes variations whose sources cannot be completely identified and controlled and are considered to be due to chance. The fluctuations may be in either direction (i.e., positive or negative bias). The chance for random error may be affected by the quality and source of reagents, the number and complexity of the steps in a procedure and the skill of the analyst performing the test. An example of this would be analyses of the same specimen, made in exactly the same way by the same analyst, yielding different results.

A system is said to be in a state of statistical control when systematic variance, random variance and the interaction between the sources of variance have been evaluated and judged to be within acceptable limits. This does not eliminate all the variability in the data, but the remaining variance is considered unimportant and reasons for its occurrence are not sought.

The reliability of lipid and lipoprotein testing can be addressed by examining survey data. Most laboratories are enrolled in proficiency testing. Two major organizations testing laboratory proficiency are the College of American Pathologists and the Centers for Disease Control (CDC). The precision or reproducibility of an assay can be readily assessed by the laboratory performing the test. Most total cholesterol assays today have within-day precision of <4% (coefficient of variation [CV]) while day-to-day precision is slightly higher, e.g., about 3 to 6% CV. With a great amount of care, one can achieve a within-day precision of ≤2% and a day-to-day precision of ≤3%.[1]

The CDC has proposed a modification of the procedure of Abell et al[2] for use as a reference method for cholesterol. This method includes hydrolysis of the cholesteryl esters, extraction with petroleum ether and color development with acetic acid-acetic anhydride-sulfuric acid reagent. With proper equipment and good technical skills, this procedure can be used to produce accurate, precise results. The alterations recently instituted allow for simultaneous analysis of a greater number of samples than was previously possible, using improved instrumentation. The CDC still utilizes this method for the assignment of "target values" on serum-calibrating materials and on quality control materials.

One way to examine how accurately laboratories perform lipid analyses is to look at proficiency surveys. The 1974 findings of the CDC proficiency testing program indicated that a large variation in results was obtained when assayed serum samples were sent to 263 licensed clinical laboratories, 250 volunteer clinical laboratories and 80 reference laboratories for total cholesterol and triglyceride determinations. Values varied by as much as ±20 to 30 mg/dl for cholesterol and ±25 to 40 mg/dl for triglycerides. This suggests that accuracy still poses a problem.

Data from the College of American Pathologists suggest that the precision of total cholesterol and triglyceride methods has improved over the years, but accuracy and interlaboratory comparability are still problematic. A recent College survey suggests that interlaboratory comparability can be further improved. For example, the mean range in values for a single cholesterol specimen was 298 ± 28.5 to 376 ± 17.1 mg/dl (mean ± standard deviation). Triglyceride values ranged from 260.4 ± 43.8 to 362.5 ± 51.2 mg/dl for 1 specimen, and from 197.6 ± 30.5 to 282.1 ± 32.7 mg/dl for another. The high density lipoprotein cholesterol results (Table I) are also a problem; the range of 25.5 ± 2.7 to 30.7 ± 4.8 mg/dl represents about a 20% difference.

These large deviations in values clearly indicate the need to improve the accuracy, precision and interlaboratory comparability of lipid and lipoprotein assays. With more than 95% of clinical laboratories perform-

ing cholesterol determinations by enzymatic means, a multitude of instrumentation/enzymatic reagent combinations are contributing to the variability of values. Previous surveys have demonstrated that the methodology, reagent source, instrumentation, standardization technique, type of standard or calibrator used can affect the accuracy and precision of interlaboratory cholesterol measurements.[3,4]

Standardization of Lipid Research Clinics' Data

Interlaboratory performance can be significantly improved when a common standardization material is used. This was clearly proved when the CDC assisted in standardizing the 12 Lipid Research Clinics (LRC) to help minimize interlaboratory and intralaboratory variability.[5] The 12 LRC laboratories used identical methods, standards, calibrators, internal quality control procedures and blind external surveillance methods. The results were compared with the reference cholesterol method.[2] The LRC laboratories also used the same sequence of standards and common procedures for instrument start-up, instrument calibration and analysis. The average cholesterol bias for the 12 laboratories was −1.3% and ranged from −0.5 to −2.0% when compared with the reference values of Abell et al.[2] The overall results indicated that a high degree of accuracy, precision and interlaboratory comparability was achieved through the rigorous standardization and control of the entire analytical procedure in the LRC laboratories. In addition, the average bias was very small and probably approaches the practical limits of accuracy that can be achieved in any collaborative multilaboratory study.

The results show that collaborative studies involving laboratories throughout the country can be done in such a way that resulting data can be legitimately pooled for analysis. Care must be taken in standardizing methodology, evaluation criteria, control pools, calibration material, etc. Internal and external quality control programs should also be implemented to monitor and assess the performance and comparability of various laboratories.

Reliability of High Density Lipoprotein Cholesterol Measurement

The CDC published a survey report that examined 130 laboratories in relation to their methods and performance in measuring high density lipoprotein cholesterol.[6] Of the 130 participating laboratories, 79 were classified as medical service, 12 as commercial analytical service, 8 as manufacturer research and development, 18 as lipid research and 12 as LRC laboratories; one was the CDC Lipid Reference Laboratory. Thus, about 60% of the reported results were generated from clinical laboratories performing diagnostic services in medical clinics or hospitals. The findings suggest that high density lipoprotein cholesterol testing is not satisfactory in many laboratories. Although most survey laboratories demonstrated adequate precision, 53% of the mean results deviated from the mean (34.5 mg/dl) of the low level high density lipoprotein cholesterol pool by >7.5% (CV). Thus, accuracy was inadequate for most laboratories. Over the entire range of high density lipoprotein cholesterol concentrations (34.5 to 59.6 mg/dl) used in the survey, 62% of the laboratories had a mean difference for one or more pools that exceeded 7.5% of the overall mean, while 50% of the laboratories exceeded 10% of the overall mean on one or more pools. Wide laboratory variation in results within some facilities suggests that poor analytical technique was responsible. The data also implied that some laboratories did not, or could not, calibrate properly.

TABLE I College of American Pathologists Comprehensive Survey (1984 participant summary)

Constituent Method/System	Labs (n)	Mean	SD	CV (%)
	Specimen C-24			
HDL cholesterol (mg/dl)				
Herparin/Mn/Ca W/Enz Quant	113	30.7	4.8	15.5
Phos/mg with Enz Quant	998	27.4	4.2	15.2
Phos/mg Non-Enz Quant	29	28.1	5.8	20.6
Dextran sulfate (500,000#MW)/mg	188	25.5	2.7	10.7
Dextran sulfate (50,000#MW)/mg	32	26.9	3.0	11.0
Dextran sulfate (other MW)/mg	149	26.7	4.0	15.0
Electrophoresis-densitometer	99	32.7	7.4	22.6
All method principles	1,642	27.6	4.5	16.3

CV = coefficient of variation; HDL = high density lipoprotein; SD = standard deviation.

Clear-cut differences owing to the methodologies used were not defined, with the exception of the electrophoresis procedures, which were imprecise and differed widely among laboratories. The CDC concluded that considerable improvement in high density lipoprotein cholesterol measurement is needed by many laboratories.

One of the major problems in many laboratories is the lack of appropriate reference material to use in determining the accuracy of their methods. In this respect, the CDC has been an invaluable resource as a lipid reference laboratory. The major thrust in their cholesterol and triglyceride standardization program, begun over 2 decades ago, was to ensure that the lipid and lipoprotein chemistries of the laboratories participating in the LRC program were rigorously standardized in terms of accuracy and precision. Since then, the CDC has allowed other, non-LRC centers to participate in its standardization and certification program and has offered its assistance in solving analytical errors to many nonparticipating members. Assayed, pooled control sera with "target values" established by reference procedures (and recently cross-checked by definitive methodology) are available for those who wish to determine the accuracy of the lipid tests used in a laboratory. Acknowledging the data of the 1980 CDC report[6] on high density lipoprotein cholesterol measurements, the CDC has begun a standardization and certification program to include high density lipoprotein cholesterol measurements to help reduce the errors associated with this test. This undertaking is important because many clinical laboratories use normal ranges or coronary artery disease risk tables based on the LRC studies.

The low density lipoprotein cholesterol/high density lipoprotein cholesterol ratio for coronary artery dis-

ease risk was developed from the Framingham data base.[7,8] The methods used in the Framingham studies were rigorously standardized by the CDC. The mean difference in plasma high density lipoprotein cholesterol concentration between those subjects confronted with coronary artery disease and those apparently normal was about 4.3 mg/dl.[8] This small difference between the 2 populations highlights the importance of ensuring that the high density lipoprotein cholesterol method is highly precise so that analytical tests reveal the true sensitivity and specificity of the method. In addition, because the high density lipoprotein cholesterol determination, high density lipoprotein cholesterol/total cholesterol ratio and low density lipoprotein cholesterol/high density lipoprotein cholesterol ratio risk tables now being used by physicians are based on the Framingham study, it is essential that clinical laboratories execute high density lipoprotein cholesterol determinations with the same accuracy and precision.

High density lipoprotein cholesterol is generally measured as the cholesterol in the supernatant solution after precipitation of apo β-containing lipoproteins. According to the College of American Pathologists (Table I), the sodium phosphotungstate method is most commonly used in the clinical laboratory. Dextran sulfate with magnesium is another precipitation procedure in use. This method was recently reported as a selected method for high density lipoprotein cholesterol testing; it was designed to optimize the conditions for removing low density lipoprotein and very low density lipoprotein, the apo β-associated lipoproteins, without excessive high density lipoprotein precipitation.[9] The dextran sulfate and heparin-$MnCl_2$ methods are generally considered the comparison methods because previous studies demonstrated good specificity for high density lipoprotein separation.[9,10]

Although electrophoresis gives a positive bias (Table I), it is still used as a means of high density lipoprotein cholesterol quantitation.[11] While conceptually it has the advantage of simultaneously obtaining the cholesterol concentration in the electrophoretically separated lipoproteins, electrophoresis is inaccurate and imprecise. This methodology should be discouraged because of the availability of other more reliable methods.

Recently, Warnick et al[12] evaluated "second generation" high density lipoprotein methods to assess their agreement on normolipidemic specimens, and on specimens with high and low concentrations of cholesterol, triglyceride and high density lipoprotein. The methods were compared using specimens with a wide range of total cholesterol, triglyceride and high density lipoprotein cholesterol values. Their study suggested that dextran sulfate, heparin-$MnCl_2$ (92 mmol/liter) and phosphotungstate-$MgCl_2$ procedures yield similar results.

It should be emphasized that high density lipoprotein cholesterol quantitation has 2 stages: isolation of the high density lipoprotein and measurement of the cholesterol in the isolated high density lipoprotein. While the first phase can be accomplished relatively easily with care and appropriate precipitating agents, the second phase can cause analytical problems; i.e., the salts used can cause interference with the cholesterol measurements, depending on the specific method selected.

Reliability of Triglyceride and Low Density Lipoprotein Measurement

The assay of triglycerides poses more problems in the general clinical laboratory. Few laboratories in the United States correct for free glycerol concentration. This has important implications in determining low density lipoprotein cholesterol because it is estimated from very low density lipoprotein cholesterol. Most clinical laboratories, for convenience, indirectly estimate very low density lipoprotein and low density lipoprotein cholesterol using the Friedewald formula, which hinges on the assumption that very low density lipoprotein cholesterol approximates *plasma* true triglyceride divided by 5. From this calculation LDL-C can be calculated as LDL-C = total C − (VLDL-C + HDL-C), where LDL is low density lipoprotein; C is cholesterol; VLDL is very low density lipoprotein; HDL is high density lipoprotein.

There are several technical problems with this technique. First, the Friedewald formula does not apply to all persons. Second, the formula is based on true triglyceride determination. Most laboratories measure total glycerol and report the value as "triglycerides." These laboratories do not want to measure true triglycerides because of the cost, inconvenience, time and the false assumption that the free glycerol level in the blood is small and relatively constant. While most nonstressed healthy persons may have free serum glycerol concentrations of 8 to 20 mg/dl, it is not uncommon to find values >75 mg/dl.[1] Thus, it is easy to see that when inaccurate triglyceride values are obtained, the estimated very low density lipoprotein cholesterol value is incorrect, leading to inaccurate estimates of low density lipoprotein cholesterol. It should also be remembered that the Friedewald formula does not apply when true triglyceride values are >400 mg/dl.

For an accurate triglyceride level, the free glycerol of the sample should be subtracted from the total glycerol (both free and that produced from saponification of the triglycerides) by a blanking procedure. Inspection of the current proficiency survey of the College of American Pathologists indicates that less than 1% of the participants correct for free glycerol in the blood. Quantitative analysis for triglycerides in serum and plasma is commonly done by hydrolyzing the triglycerides and then determining glycerol enzymatically or chemically. When this is done, however, not only glycerol derived from the triglycerides but also the unesterified "free" glycerol is measured. Either 2 analyses must be performed, one before and one after the hydrolysis step, or the 2 serum constituents have to be separated by extraction or by solvent partition.

Glycerol primarily comes from the adipose tissue via lipolysis of stored triglycerides. The triglyceride lipase that regulates the rate of triglyceride breakdown to free fatty acid and glycerol is sensitive to hormones. Epinephrine, glucagon, thyroxine and growth hor-

mone will potentiate the activity of this enzyme, which, in turn, causes more free fatty acid and glycerol output into the blood. It is understandable, then, that any stressful situation creates a situation in which a high free glycerol concentration can occur. Some known conditions that can contribute to high glycerol levels in the blood are stress (epinephrine effect), mannitol infusion, treatment with nitroglycerin, diabetes mellitus, glycerol-coated stopper used in Vacutainer tubes®, certain liver diseases and hemodialysis in cases of renal failure.[1] Because there is a risk involved in calculating the free triglyceride concentrations by using factors of percentages, glycerol blanking is necessary for accurate triglyceride analysis.

Reliability of Lipid and Lipoprotein Testing (II)

JOSEPH E. O'BRIEN, MD

There is enormous interest in the measurement of blood lipids, both by physicians and by patients. Proficiency testing of laboratories by the College of American Pathologists and the Centers for Disease Control (CDC) has provided a large data base concerning such measurements. Examination of these data reveals that laboratories perform in an acceptable way. However, in the College's surveys, the coefficient of variation (CV) for cholesterol measurements averages about 6%. A 6% CV means that there is a 95% probability that a cholesterol value of 260 mg/dl will be reported between 229 and 291 mg/dl. The survey shows further that the CV itself may vary from 2.5 to 9.5%, depending on the laboratory, method and instruments. A cholesterol value of 260 mg/dl with a CV of 9.5% will be reported in a range of 210 to 309 mg/dl.

Similar data can be obtained from the CDC's proficiency testing, where the CV has been reported to average from 9 to 10%. At a cholesterol level of 135 mg/dl, a 10% CV implies reported values ranging from 108 to 162 mg/dl. The CDC data also show that the CV ranged from 3 to 18% in different laboratories.

The data are distressing, but physicians and patients see less variability in results since, generally, a patient's cholesterol is analyzed in a single laboratory, and the precision data from a single laboratory are much better than the proficiency data derived from all laboratories. For example, our laboratory performs 10,000 cholesterol assays a day. Our internal quality control measures indicate that at a level of 150 mg/dl our CV is 2.9%. At a level of 325 mg/dl, the CV is 3.5%. Therefore, at a level of 200 mg/dl the possible error is ±12 mg/dl.

High density lipoprotein cholesterol determinations are a greater problem. The CDC data show that for high density lipoprotein cholesterol, the CV at a level of 35 mg/dl is 15%. Therefore, throughout the United States, from laboratory to laboratory, a specimen may yield a value of anywhere from 25 to 45 mg/dl. Again, the data from a single laboratory are much better. In our laboratory, the CV is 5%, which means that in any particular patient, a value of 35 mg/dl has a 95% probability of being reported between 31.5 and 38.5 mg/dl.

Our laboratory has recently begun to receive requests for apoprotein testing. The demand is going to increase, but the accuracy and proficiency data indicate that there are significant problems with the current technology.

Clearly, the way tests are standardized needs to be improved. We need to tighten the criteria for acceptable behavior. While the performance within single laboratories has been acceptable, the need for standardization of our testing methods is evident. Establishing an arbitrary position concerning an acceptable CV is one possibility.

Discussion

Dr. Grundy (Dallas, Texas): Dr. O'Brien, how should the physician interpret a high density lipoprotein cholesterol value in terms of deciding on a therapy for a patient? Would you recommend that multiple measurements be made before embarking on some particular therapy?

Dr. O'Brien (Teterboro, New Jersey): As a general rule, if the physician is going to initiate therapy that will have a dramatic impact on the patient's life, then it is necessary that a second value be obtained. More than 60% of the time, the range reported will be much better than what I mentioned. But I think it is important that physicians do understand the outside limits of today's precision.

Dr. Rifkind (Bethesda, Maryland): Within limits, one can tolerate a degree of imprecision in the measurement of total cholesterol that one cannot tolerate in the measurement of high density lipoprotein cholesterol. A 5- or 10-mg error in total cholesterol can be accommodated. I do not think it is likely to interfere with the diagnostic process and the levels of risk that are estimated from it, but a corresponding error when you are measuring high density lipoprotein cholesterol, which has a mean of about 45 mg/dl, can give a totally unacceptable range of risk. I think physicians ought to realize that reasonable confidence can be placed in the total cholesterol measurement, but in the area of high density lipoprotein cholesterol, they are susceptible to major errors in assessing a patient.

Dr. Roberts (Bethesda, Maryland): I have 2 questions. First, as I understand it, the Lipid Research Clinics determinations were plasma, not serum, values for total cholesterol and low density lipoprotein cholesterol. What is the difference overall in values obtained from serum versus those obtained from plasma, and which of the two is preferable? Second, I understand that in most studies of systemic hypertension, 3 different blood pressures are taken, and when the level is above a certain number during 2 of those 3 determinations, then the patient is given treatment. I recently examined the chart of a patient who had 20 total cholesterol values determined in the same hospital over a 1-year period. Those 20 values range from 185 to 240 mg/dl. What is the true value of the total cholesterol in that particular patient? Do you average 20 values? How do you handle that type of data?

Dr. O'Brien: I think that within a single facility the range that you describe is too large and unacceptable. I think the patient's value is probably the same in each analysis, and the variation you report is a variation in the behavior of the laboratory. In a situation like that, I think that rather than do something for the patient, we should go to the laboratory and see what is wrong. Regarding serum versus plasma, I always speak from the perspective of someone who is interested in mass screening. We have chosen to do that efficiently on a multichannel analyzer, and to do that we need serum. We did a small study that showed that the difference between serum and plasma was very small and not clinically significant.

Dr. Rifkind: Perhaps I could speak on the serum–plasma differences, as they were systematically evaluated in the Lipid Research Clinics program. We chose plasma, not because we necessarily advocated it as the ideal for the conventional clinical context, but because of the specialized studies that we performed; in particular, for the more detailed analysis of lipoproteins, we had to use EDTA plasma. Because of the dilution effect of the EDTA, plasma provides results that are approximately 2 to 3% lower than serum values. In general, because of convenience considerations and the like, one would expect serum cholesterol to be measured much more often than plasma cholesterol.

Dr. LaRosa (Washington, D.C.): Perhaps it might be worthwhile to emphasize—for those who deal with patients on a day-to-day basis—that besides genetics, diet and the general health of the patient, a multitude of other factors are important in determining the cholesterol level. A patient's cholesterol value can change dramatically in a year. I think because of that there is a need to perform at least a few cholesterol determinations before deciding that a given level is correct for the patient.

Dr. Rifkind: Several speakers have commented on the variations in cholesterol in repeated measurements over time. Some of these changes come from diet, concurrent medications, such as estrogens in women, and intercurrent illness. For example, it is perhaps not well known that cholesterol levels drop dramatically in the weeks after a myocardial infarction. The physician can deal with that problem by standardizing the conditions under which a cholesterol measurement is taken. He should ask that the individual be on the usual diet, be out of the hospital, not take medications that are likely to alter cholesterol levels and that the measurement, as several speakers have indicated, be done on 2 or 3 occasions. Under such circumstances, cholesterol levels are much less likely to vary and reliable interpretation of them is possible.

Dr. Grundy: I have heard that if you are in a standing or sitting position, you will have a higher cholesterol than in a prone position? Is that correct?

Dr. Rifkind: That is correct, and, for example, in the Lipid Research Clinics program, where careful cholesterol measurements on repeated occasions over many years were required, we specified that individuals be recumbent for several minutes and that the tourniquet only be applied for a limited time. Some precautions along these lines ought to be taken in acquiring a sample for cholesterol determination.

Dr. Grundy: It is obviously not possible to do ultracentrifugation in clinical laboratories, which might improve accuracy. We are left, therefore, with having to do an estimate of the low density lipoprotein cholesterol and, to some extent,

of the high density lipoprotein cholesterol. How do the triglyceride levels affect the measurements and what precautions should be taken in patients whose triglyceride levels are high?

Dr. Naito (Cleveland, Ohio): Triglyceride levels can affect the estimation of high density lipoprotein cholesterol and low density lipoprotein cholesterol. If the laboratories do not remove the chylomicrons, if present, by ultracentrifugation, one will get a volume displacement problem. Therefore, your determination of triglycerides will be inaccurate. Second, the Friedewald formula no longer holds in any sample with a triglyceride concentration in excess of 400 mg/dl. At this point, the institution should try and send the sample out to a laboratory where the very low density lipoprotein can be isolated by preparative ultracentrifugation so that a more accurate estimation of the low density lipoprotein cholesterol can be made. In hypertriglyceridemic samples, in which one will have increased pre-β-lipoprotein, interference with the precipitation technique can result, which will cause erroneous values.

Finally, most clinical laboratories throughout the country still do not measure true triglycerides. Rather, they measure total glycerol in the blood and report the values as "triglycerides." If a person does this, one cannot estimate very low density lipoprotein cholesterol by the Friedewald formula because it is based on true triglyceride measurements. This means that low density lipoprotein cholesterol estimations will be inaccurate and unreliable if one doesn't correct for the free glycerol in the blood.

Defining Coronary Risks in a Reference Range for Total Cholesterol and Lipoprotein Values: A Problem Yet To Be Solved

BRUCE M. McMANUS, MD, PhD

The *US News and World Report* (February 18, 1985) contained an article entitled, "The English Language: Out to Conquer the World," in which the term "gobbledygook" was defined as that "normally occurring, abnormal occurrence." The authors were referring to the nuclear industry's conception of something that goes wrong all of the time.

In some respects, the problem of defining a level of cholesterol in the blood at which physicians should intervene and treat a patient is directly related to this "normally occurring, abnormal occurrence." In individual prospective studies and from analysis of pooled data from national and international studies, the evidence for an association between coronary atherosclerotic disease and elevated blood cholesterol levels is very strong.[1,2] However, the specific cholesterol level at which physicians should intervene is unclear. This is due in part to the convention of using various reference populations as a basis for reporting laboratory cholesterol ranges.

The important issue is resolution of the dichotomy between the values reported by a clinical laboratory for total serum cholesterol (acceptability defined by reference ranges) and the values associated with increased risk. When should a practicing physician intervene? What effect should knowledge of the high density lipoprotein level have on physician intervention?

Let me first address the question of why it is important to have a denotation of risk. The reliability of laboratory assays is of concern.[3] Unreliability is becoming less of a problem, and, if standardized conditions are used to obtain the blood sample from the patient for determination of lipids, one can assume that reasonable and reliable cholesterol levels are measured. With reliable levels, one can then discriminate between those people who are healthy, and those who are occultly or overtly diseased and require treatment. Treatment for familial or nonfamilial hyperlipidemia should begin with dietary intervention and increase in rigor in accordance with dietary program guidelines such as those of the American Heart Association. Only when dietary modification has been maximized should single or multiple hypolipidemic agents be tried.

An important question that follows is: On which side of the coin does one wish to err? Most authorities now agree that somewhere between 25 and 50% of adult Americans are recorded as false negatives for hypercholesterolemia. On the other hand, virtually no one is being recorded as a false positive for hypercholesterolemia. This is very worrisome because hypercholesterolemia is associated with significant atherosclerotic disease. Overlap of the 2 Gaussian curves developed from the Framingham data for blood cholesterol levels of people who eventually manifest coronary artery disease and those who do not does not diminish the concern.[4] The fact is that people with a false negative classification for hypercholesterolemia are analogous to those with unrecognized systemic hypertension. Both groups are walking time bombs.

It is not the fault of the clinical laboratories that, for the past 30 years, they have used a reference range for defining "acceptable limits" for blood cholesterol. Reference ranges are used for all substances measured in body fluids, including those in blood. Thus, the use of a statistically developed curve to define a population parameter is a traditional laboratory approach. The difficulty is that with cholesterol, the level is not normal in a great number of people. Confusion arises when, for example, a laboratory report is issued with no limiting cholesterol value given to denote increased risk of atherosclerotic disease. Only an upper limit of the reference range is provided, usually between 275 and 330 mg/dl. What the report means is left to the imagination of the clinical physician. When a patient's cholesterol level is 275 mg/dl, which is a level considered high enough to enter people in the Lipid Research Clinics-Coronary Primary Prevention Trial, what is a physician to do when the reference range goes to 330 mg/dl? At a blood cholesterol level of 275 mg/dl, given

From the Departments of Pediatrics, Pathology and Laboratory Medicine, University of Nebraska Medical Center, Omaha, Nebraska.

Address for reprints: Bruce M. McManus, MD, PhD, University of Nebraska Medical Center, Wittson Hall, 42nd and Dewey Avenue, Omaha, Nebraska 68105.

the quintile information from the Framingham study,[4] a person is at a distinctly increased risk for coronary artery disease, yet most laboratories in the United States would not alert the patient or his physician of a need to change the patient's diet.

We recently completed a survey of all academic laboratories in Canada and the U.S.[5,6] We obtained the reference ranges for total serum cholesterol or low density lipoprotein cholesterol, the source of the reference ranges and the level at which these laboratories defined an increased risk. The defined upper limit of "normal" for total blood cholesterol ranged from 220 to 330 mg/dl.

We are left in a bit of a quandry. How can we allow reference ranges to stand as they currently are, given that they represent the populations sampled, while we identify a cholesterol level at which a physician should begin to consider intervention? The evidence for an association between coronary artery disease and certain elevated levels of blood cholesterol is strong enough to suggest that if one exceeds 200 to 220 mg/dl blood cholesterol, overall, one is at increased risk for the development of atherosclerotic disease. Laboratories must find a better method for denoting risk.

The percentage distribution of the major lipoproteins in a total cholesterol measurement must be considered. The high density lipoprotein cholesterol and fasting triglycerides can be used to determine an indirect estimate of low density lipoprotein cholesterol and very low density lipoprotein cholesterol using the Friedewald formula. Then one can make an informed decision about what a total cholesterol level >220 mg/dl means in a given patient. Thus, if a patient has a cholesterol level of 250 mg/dl, but his absolute high density lipoprotein cholesterol value is greater than 75 mg/dl or the percent of high density lipoprotein cholesterol is relatively high, he will no doubt be protected against the development of atherosclerotic disease. On the other hand, a person with a low absolute or relative high density lipoprotein cholesterol but the same total cholesterol level (250 mg/dl) would be at an increased risk. The 2 patients may be managed entirely differently, largely on the inference that low density lipoprotein cholesterol is unhealthily high in 1 patient and not in the other.

The nagging questions about ideal, acceptable, optimal or healthy cholesterol levels are perhaps the most difficult we face in the whole blood lipid–coronary risk matter. In the initial abstracts of the expert panelists of the recent National Institutes of Health Consensus Conference on Lowering Blood Cholesterol, for example, only four ventured an approximation of what the upper limit of a desirable cholesterol level should be. Of course, the consensus statement implied that a total serum cholesterol value of approximately 200 mg/dl is equivalent to mild risk in the young adult, whereas a level >260 mg/dl is equivalent to high risk in people over 40 years of age. Thus, some confusion remains as to what level is the one at which the physician should suggest therapeutic intervention.

The stringency of defining an upper limit of acceptability for total serum cholesterol must be adapted in light of, and applied in appreciation of, the degree of hypercholesterolemia that may exist. People who are far above the limit of acceptability may never be able to obtain a level low enough to fall within the ideal range by reasonable medical intervention. This may be very discouraging to the physician and to patients who are in the high 200 and 300 mg/dl range. The mutual goals of physicians and patients will be different for patients with cholesterol levels in the mid to low 200 range.

It is important to emphasize that the responsibility for transmitting the significance of a lipid value to the patient, whatever that value, is a joint responsibility of the clinical laboratorian and the physician. Neither one can absolve himself of the responsibility to interpret and provide "cholesterol" information. Any interpretation must be done in light of the patient's clinical condition and, especially, in light of all other known quantifiable risks for atherosclerotic disease.

Defining a Reference Range for Total Cholesterol and Lipoprotein Values

JOHN C. LaROSA, MD

Physicians should limit themselves to measuring total cholesterol, total triglyceride and high density lipoprotein (HDL) cholesterol levels. Lipoprotein electrophoresis, which is still done by many laboratories, has little clinical utility as a screening device, although it may be useful for detecting chylomicrons and broad β lipoproteins.

There is no universal agreement about the value of HDL cholesterol determinations as a screening device. They are useful, although their reliability in many laboratories is still questionable. HDL subfractions are not as yet of any clinical value. Lipoprotein-apoprotein measurements are of general clinical usefulness, although apoAI and apoB determinations may ultimately be more reliable than HDL cholesterol and low density lipoprotein (LDL) cholesterol determinations.

The normal values for total cholesterol, total triglyceride and HDL cholesterol should be based on some estimate of the associated risk of cardiovascular disease, rather than on means and standard deviations. Although such values are arbitrary, they are no more so than a blood pressure level of 140/90 mm Hg as a measure of hypertension. The precise meaning of such levels will be debated for a long time, but they give the practicing physician some way of dividing patients into those who require therapeutic attention and those who do not.

For total cholesterol, a value of 240 mg/dl is appropriate for delineating associated coronary risk. This is essentially the value that the recent Consensus Conference on Cholesterol recommended for adults as requiring intervention.[1] On the basis of less firm data, an HDL cholesterol of ≤40 mg/dl should be considered as "abnormal".[2] For triglycerides, a level of about 250 mg/dl is "abnormal". That level roughly corresponds to the 95th percentile for middle-aged Americans, and was the level identified by a recent National Institutes of Health Consensus Conference on Triglycerides as requiring intervention.[3]

As a practical consideration in adults, it is relatively unimportant for the practicing physician to correct these numbers for age or for sex; both risk of cardiovascular disease and cholesterol and triglyceride levels increase with age. When these numbers are applied to children, they are even more likely to identify individuals with substantial metabolic alterations. It should be remembered, however, that plasma lipid levels change dramatically during growth and development, and we must approach therapeutic decisions in children with even greater caution.

The LDL/HDL cholesterol ratio can, of course, be derived from these 3 basic tests and has been promoted as clinically useful. Ratios, however, should be viewed with some skepticism. A patient with elevated total and LDL cholesterol, for example, should not be reassured because the HDL cholesterol is also high. Ratios should never be used in place of the absolute numbers.

LDL cholesterol can be calculated using the Friedewald formula.[4] It must be remembered that this formula is only reliable when the triglyceride is <400 mg/dl. A calculated LDL level is not very useful because it does not provide more information than the total cholesterol level does when HDL and triglyceride levels are known.

Occasionally, persons whose total cholesterol is in the mid-200 mg/dl range will be found to have high HDL cholesterol rather than LDL cholesterol levels. Women taking hormone preparations and those who are athletic will often show elevated HDL cholesterol. These examples provide another reason for measuring HDL cholesterol levels, because it would be inappropriate to intervene in such individuals based simply on the total cholesterol level.

On the other hand, there are people in whom cholesterol levels are normal, triglycerides are normal and HDL cholesterol levels are very low. Most of these people are genetically deficient in HDL cholesterol. They comprise an as yet undefined portion of people with coronary disease who have been characterized as having "no risk factors". In the Lipid Research Clinics Program Prevalence Study, 2 to 3% of adult men had mean HDL cholesterol levels that were <30 mg/dl, even though their total cholesterol and total triglycer-

ides were normal.[5] It must be asked, of course, of what value it is to find such people when we are not at all certain how we should be treating patients with low HDL cholesterol.

It has been proposed by some that persons with low HDL cholesterol be treated with medication that lowers their LDL cholesterol, thus bringing their ratio into better balance, even though their total or LDL cholesterol may not be elevated. There is no evidence at this time that such a regimen is beneficial.

Discussion

Dr. Gotto (Houston, Texas): I agree with Dr. LaRosa that a level defining what we mean by hypercholesterolemia should be adopted, even though it may be arbitrary. I am perfectly agreeable to using 240 mg/dl as an arbitrary measure for defining moderate risk of hypercholesterolemia. I think it would be a mistake, however, to lose sight of the fact that cholesterol values of less than 240 mg/dl are still potentially dangerous. If one looks at the average cholesterol value of men who have a positive coronary arteriogram or who have coronary artery disease, it is only about 230 mg/dl. This is only marginally higher than the mean in the American population, which is 215 to 220 mg/dl. Therefore, it is important that in defining hyperlipidemia we do not consider a normal value the same as a safe value, because a cholesterol of 220 or 230 mg/dl, in my opinion, is not a safe value.

If one looks at what is considered a low level of high density lipoprotein cholesterol, it is important again to further distinguish between what is considered a normal and a safe total cholesterol. A low high density lipoprotein cholesterol in American society may be much more important than a low value measured in an African or Asian society. What makes a high density lipoprotein cholesterol of 20 or 25 mg/dl dangerous is the fact that the total cholesterol may be 200 or 210 mg/dl, rather than 160 mg/dl. I am not convinced that there is evidence that a low level of high density lipoprotein cholesterol per se is associated with risk if the total levels of cholesterol and low density lipoprotein cholesterol are sufficiently low, as they are in nonindustrialized societies. But in American society, a cholesterol level of 200 mg/dl, which is considered normal, would be too high with a high density lipoprotein cholesterol of 20 mg/dl.

Dr. Roberts (Bethesda, Maryland): It seems to me that the most important issue raised at this conference is determining the normal level of total cholesterol, low density lipoprotein cholesterol and high density lipoprotein cholesterol. It seems to me that the cutoff levels that have been mentioned are those at which cholesterol-reducing therapy should be initiated. We also need a level at which one is going to diminish the risk of coronary disease or arteriosclerosis anywhere in the body, i.e., the level at which coronary disease is preventable. I would say that that level has to be around 150 mg/dl in an adult. If one's level is lower than that, then the chance of getting coronary disease that would be of clinical consequence is virtually nil.

There really should be 4 levels, not just one. I am fully aware that among Americans, only 5% of those over 40 years of age have total cholesterol levels under 150 mg/dl, but this is the group in whom coronary disease is preventable. The second level would be that level at which the risk of getting coronary disease is lowered. The third level would be where diet therapy is initiated to lower the cholesterol and the fourth level would be where drug therapy is initiated in addition to diet therapy.

If we are going to improve the health of this nation, if we are going to prevent coronary disease, it is ridiculous to be satisfied with a cholesterol level of 240 mg/dl. We have got to make that level much lower.

Dr. LaRosa (Washington, D.C.): I do not disagree with either Dr. Gotto or Dr. Roberts. But I still go to community hospitals and talk to physicians who do not treat patients whose cholesterol levels are less than 300, 350 or even 400 mg/dl because we have given them too many levels to deal with. We have given them more information than they can reasonably base a practice on. While we might all consider 240 mg/dl as too high, it is not considered too high by the clinicians who are taking care of patients because of the confusion that has existed in this field and because of the fact that laboratories have traditionally recorded such values as a normal range. I would guess that many practicing physicians would not consider any kind of intervention, even dietary, until the level is 300 mg/dl.

Dr. O'Brien (Teterboro, New Jersey): We will shortly begin to report cholesterol values as a percentile, ranked by age and sex. So the 75th percentile for a 24-year-old man will be 200 mg/dl, and the 75th percentile for a 49-year-old man will be 249 mg/dl.

Dr. McManus (Omaha, Nebraska): Why would you be less likely to be concerned about a middle-aged man with a cholesterol of 220 mg/dl than a 25-year-old man with a cholesterol of 220 mg/dl?

Dr. O'Brien: There is an increase in cholesterol with age, and we assume that it is necessarily a function of disease. There is some change in cholesterol that may be an adaptive mechanism to aging. I would say that a cholesterol value of around 200 mg/dl is more appropriate for a 20- or 25-year-old. But could you reasonably give a cholesterol value of 200 mg/dl as a target for a 59-year-old-man? That might lead to frustration and abandonment of the treatment programs.

Dr. LaRosa: I may end up in the minority, but I don't agree with that approach. I think percentile rankings lead to an unnecessary amount of confusion, and I am becoming less and less convinced that we should make allowances for the so-called "normal" effect of aging.

Risk Criteria

BASIL M. RIFKIND, MD

This article will draw heavily on the recent report of the Consensus Development Conference.[1] One of the questions asked of the members of the conference panel was, did they believe there was a causal relation between cholesterol and coronary artery disease (CAD)? For many of us who have been in the field for many years, this hardly seemed necessary to ask but, given the prior controversy regarding cholesterol and CAD, it was a question that had to be looked at in the light of all the available evidence. The panel unanimously stated that the evidence obtained from genetic, experimental, epidemiologic and clinical investigations, as well as from clinical intervention investigations, overwhelmingly supports a causal relation between blood cholesterol levels and CAD. This is the scientific foundation, drawn from a widely based multidisciplinary approach, upon which the other recommendations of the Consensus Conference are based.

It should be emphasized that the Consensus Conference essentially presented 2 mutually compatible strategies. Review of the available data suggests that levels above 200 to 230 mg/dl are associated with an increased risk of developing premature CAD. It is staggering to realize that this represents more than 50% of the adult population of the United States. I think it is fair to say that this estimate is deliberately conservative. Some argue that a person's blood cholesterol level must be below 150 mg/dl before the risk of CAD is eliminated. In any event, the conference panel agreed that at least 50% of Americans have a significantly increased coronary risk because of high cholesterol levels. Any strategy has to direct attention to this large group, rather than to any subgroup of the population.

The first recommendation of the Consensus Conference was that the entire American public must be encouraged to reduce cholesterol levels; i.e., the curve of the cholesterol distribution must be moved to the left. The panel suggested that the target levels for cholesterol should be about 200 mg/dl for people over 30, and about 180 mg/dl for people under 30. These levels should not be regarded as scientifically precise points. The target levels may actually be lower than this, but the question of practicality was also taken into consideration. The panel wanted to recommend to the entire U.S. population something that can be done at this time. If these recommendations are successful, then consideration could be given to whether new target levels are desirable. The dietary recommendations were to moderate fat intake to about 30% of total energy intake (it is presently about 40%), to reduce saturated fat to ≤10%, to increase polyunsaturated fat, but to no more than 10% and to moderate dietary cholesterol intake to 250 to 300 mg/day. These should be seen as moderate dietary recommendations. Others call for more stringent dietary change. These dietary recommendations are designed to shift the cholesterol levels of the population down toward the target levels.

When defining target levels, we are not defining them for one group and not another. Middle-aged people who fall below the level of 240 mg/dl are often still at increased risk of CAD and the dietary recommendations apply to them, as well. The purpose of target levels is to define a group who require the attention of a rather limited medical resource; we can only apply the one-on-one approach that characterizes conventional medical care to a limited fraction of the population.

Accordingly, the second set of recommendations was directed to that smaller proportion of the population who are at particularly increased risk for CAD. They need intensive physician interaction and counseling from nutritionists, and will have to pay repeated visits before their cholesterol levels are brought under control. In defining the high cholesterol groups, there was unanimity on the panel's part that about 20 to 25% of the population might be defined as at high risk. About 20%, which is the top quintile of the American cholesterol distribution, accounts for about 40% of all myocardial infarctions, which is a substantial number. The other side of that coin is that 60% is accounted for by people below the top quintile, namely the public at large.

The Consensus Conference offered specific recommendations for target levels. Some of the issues that were considered in formulating these recommendations will be briefly discussed. If we want precision in selecting target levels, for example, if we want to take into account age and sex, then a rather complex series

From the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland.

Address for reprints: Basil M. Rifkind, MD, Lipid Metabolism/Atherogenesis Branch, National Heart, Lung, and Blood Institute, 7550 Wisconsin Avenue, Federal Building, Room 401, Bethesda, Maryland 20205.

of levels would evolve, and physicians will not use them. If levels are overly simplified, there is a danger that all the issues will not be addressed, and significant segments of the population will be neglected.

The Conference's compromise is a useful and simple one, and there are indications that it is already being adopted. Their simple tabulation of target levels was rapidly and frequently reproduced in both consumer and professional medical publications.

The Conference defined 2 levels of risk: a group of high-risk subjects, above the ninetieth percentile (the top 10% of the adult population), and a group of moderate-risk subjects, between the seventy-fifth and ninetieth percentile (Table I). The high-risk subjects were, for ages 20 to 29, >220 mg/dl, for ages 30 to 39, >240 mg/dl and for 40 and over, >260 mg/dl. Corresponding levels for the moderate-risk subjects were 20 mg lower in each case; i.e., for ages 20 to 29, 200 mg/dl, for ages 30 to 39, 220 mg/dl and over age 40, 240 mg/dl. These target levels were applied to men and women, again with some sacrifice of accuracy, but with the advantage of practicality.

This is a fairly simple tabulation. It tries to marry simplicity with application, and it does not represent an all-or-none approach. To reiterate, the target levels define a group that needs special attention. Adults aged 30 years or over who fall below the moderate-risk levels, but who are above the target values of 200 mg/dl, still need advice. They still need to bring a cholesterol level of, for example, 230 mg/dl down below the target level.

What shall we do with these levels? The 25% of the population that will ultimately be defined as at high risk is not an inconsiderable burden or challenge to the medical care system. The Conference indicated that, ultimately, all Americans should know their cholesterol levels, just as it is recommended that individuals know their blood pressure and cigarette smoking levels, and do something about them. All Americans should have their cholesterol levels determined. Mass screening in various guises must be instituted eventually. The Conference, however, was justifiably reticent about immediate mass screening. The medical system would be overwhelmed if 50 million Americans were identified as needing one-on-one medical management.

TABLE I **The National Institutes of Health Consensus Recommendation on Total Cholesterol Values for Selecting Adults at Moderate and High Risk Requiring Treatment**

Age (years)	Moderate Risk (75–90th percentile)	High Risk (>90th percentile)
20–29	>200 mg/dl	>220 mg/dl
30–39	>220 mg/dl	>240 mg/dl
≥40	>240 mg/dl	>260 mg/dl

From reference 1.

The Conference Report did note that a high proportion of U.S. adults see their doctors in a given year, and the first approach to screening should be to have a cholesterol determination during a person's first visit to the doctor. Over time, a large proportion of the adult population would then be screened. In the interim, we need to investigate screening approaches and to conduct feasibility studies of how best to screen and how to deal with those individuals that are then identified as being at risk.

Measurement of Lipoproteins

GERALD R. COOPER, MD, PhD

The issue of which lipoproteins should be measured can best be addressed by asking 2 questions. The first is which lipoproteins should be considered for measurement to provide clinical data? The total cholesterol, which really measures all of the lipoproteins, is a very complex risk factor and cannot stand alone. Triglyceride, which measures very low density lipoproteins, provides information about our triglyceride and intermediary metabolism. High density lipoprotein (HDL) cholesterol is thought to be a risk factor in low concentrations, while low density lipoprotein (LDL) cholesterol is a risk factor in relatively higher concentrations. Intermediate density lipoprotein (IDL) is measured to detect genetic defects; in high concentration it is considered a risk factor. Chylomicrons are remnants and are highly suspected of being involved as a risk factor in the development of atherosclerosis. The most important tests from a clinical standpoint, therefore, are total cholesterol, total triglyceride and HDL cholesterol.

The second question is which lipoproteins should be measured to serve the various functions in the laboratory? The simplest screening test is the total cholesterol determination with observation for turbidity. For a more thorough evaluation, one should measure

From the Centers for Disease Control, Atlanta, Georgia.

Address for reprints: Gerald R. Cooper, MD, PhD, Clinical Chemistry Division, Centers for Disease Control, Building 17, Room 1103, Atlanta, Georgia 30333.

total cholesterol, HDL cholesterol and turbidity. Turbidity is measured because any triglyceride in humans above 250 mg/dl can usually be detected just by observation.

For clinical laboratory evaluation, one must begin with the same assays: total cholesterol, triglyceride, HDL cholesterol and turbidity. This should be followed by determination of cholesterol ratios. In lipid follow-up studies, total cholesterol, triglyceride, HDL cholesterol and chylomicron determinations should be performed. Electrophoresis in follow-up studies can detect any unique proteins, especially IDL hyperlipidemia. In our experience, 95% of type III or IDL hyperlipidemia is detected with the usual electrophoresis and a gel electrophoresis. Apoprotein defects should be considered in follow-up studies; a specimen should be sent to a reference laboratory for IDL, apo-E isoform and C-II tests for genetic determination of type IV hyperlipidemia and other disorders. While there is great potential for apoprotein measurements, there is now a 75% error rate associated with these measurements among laboratories. There are also standardization and interpretation errors. A standardization program is being developed by the International Union of Immunologic Societies, the Centers for Disease Control and the National Institutes of Health.

Another important issue is the timing and frequency of plasma lipoprotein determinations. In cord blood, a total cholesterol can be helpful in identifying suspected cases of hyperlipidemia. In the age group between 3 and 20 years, a total cholesterol and HDL cholesterol should be determined in suspected cases. For all persons between 20 and 40 years, total cholesterol should be measured to detect and prevent disease. In persons between 40 and 60 years, it is important to remeasure lipids to evaluate the effects of aging.

The frequency of analyses may vary. For example, HDL cholesterol is a constant measurement in a person unless changes in life-style occur. To monitor changes of the powerful causal agent—LDL cholesterol—we must follow with a test of total cholesterol because as long as conditions are controlled, the total cholesterol will reflect changes in the LDL cholesterol.

Discussion

Dr. McManus (Omaha, Nebraska): I would like to underscore what Dr. Cooper is saying about obtaining a reliable cholesterol value. Multiple values at different points in life may be useful for different purposes in the management of patients, but I think we all are aware that there are many patients today who do not have a single cholesterol determination in the clinic or hospital record, and yet they may have been hospitalized numerous times. Considering the low cost of a total cholesterol assay relative to other types of tests, and accepting its limitations, I think that having at least a single total cholesterol at some time during adult life is nearly mandatory for proper follow-up of all patients.

I have a question for Dr. Gotto. As an advocate of a single range for cholesterol values—that is neither sex- nor age-related—for simplicity's sake, I am confused about the significance of the aging curves in serum cholesterol. I think this is similar to the way in which "essential" hypertension received this designation; that is, blood pressure was "supposed to" rise as a normal aging phenomenon in our population. Total cholesterol is now also expected to rise with age. What, if anything, does decreased capacity of liver receptors like the low density lipoprotein receptor in an otherwise nondiseased liver have to do with this phenomenon? Is receptor activity a major determinant, or is it something to do with absorption of cholesterol, or do we know? Is this something we should be isolating in efforts to understand the pathobiologic significance of the aging curve?

Dr. Gotto (Houston, Texas): We do not know why the cholesterol level increases with age. We don't really know the role of diet in this, and we do not know how much cholesterol rises with age in nonindustrialized societies after adolescence. In all societies cholesterol increases with age, up until early adulthood. In Western society, cholesterol continues to increase, at least up to age 65. It is certainly possible that a high-fat diet over a long period of time could suppress the level of low density lipoprotein receptors in the liver and as a result contribute to this rise in low density lipoprotein and total cholesterol, but I would have to emphasize that it is speculative at this point.

In terms of relative risk, I think there is no question that the relative risk increases as the cholesterol increases with age. We can divide relative risk on the basis of percentile values of cholesterol. On the other hand, we probably should not feel more secure with a cholesterol of 240 mg/dl at age 50 years than we should at age 20 years. At age 20 years, it just represents that much more of a risk than it does at age 50.

I wanted to ask Dr. Cooper a question. I understood you to say that levels of high density lipoprotein and of triglyceride, if measured under basal conditions, do not vary that much. My comment is that patients usually are not in the same state when they come back to visit the physician. We have done measurements in persons who have been put on exercise programs, for example, and we have found that over a period of a year the high density lipoprotein cholesterol may go from 40 mg/dl to 80 to 100 mg/dl, in some cases with prolonged periods of physician training and individual exercise. Unfortunately, within a week or 2 after stopping the exercise, the high density lipoprotein goes back down. In clinical practice, triglycercide is very variable. The patient may lose or gain a few pounds and the fasting triglyceride varies quite remarkably. In terms of actual clinical practice, therefore, while there is less variation of high density lipoprotein, triglycerides vary quite widely from one patient visit to another, unless there is some change in physical activity, alcohol consumption or intake of a new drug.

Dr. Cooper (Atlanta, Georgia): If you are monitoring therapy in a patient who does not have a fairly constant lifestyle, then I agree you have to really use a battery of tests.

Dr. Grundy (Dallas, Texas): How often should a person have cholesterol measured?

Dr. Roberts (Bethesda, Maryland): It seems to me that everyone who is admitted to a hospital in this country today should have at least a total cholesterol test. Although the hospital may not be the best place to do this, we never know the cholesterol level of most patients who are seen in my pathology laboratory who have had fatal coronary disease. It is really the exception to know.

Dr. Rifkind (Bethesda, Maryland): We know that only a handful of Americans know their cholesterol level. It is important to take the same approach to cholesterol that has been so successfully taken with blood pressure. Adults should have a cholesterol check and if the cholesterol is normal then it might be repeated at 5-year intervals. If it is abnormal, obviously the situation changes. The data that were used in the Consensus Conference were from the National Survey of Health Statistics, which indicated that a majority of American adults see their physicians at least once a year. If at these visits, a routine sample was taken—it need not be a fasting sample—then most Americans would soon know their cholesterol levels.

Dr. Grundy: Dr. Gotto, what are some simple, rapid methods of measurement that may facilitate the cholesterol screening process?

Dr. Gotto: I am aware of 3 companies that are currently working on methods for measuring cholesterol from a finger prick. This measurement can be carried out in 2 to 3 minutes, and does not require a venipuncture. The methods are based on enzymatic measurement of cholesterol, and they appear to have a good degree of precision and accuracy. The cost is expected to be $1 or less. With the development of this technology for measuring cholesterol, it is conceivable that screening could be done on a massive basis at work, school, shopping centers and airports.

Interpreting Lipid Values from the Clinical Perspective

ANTONIO M. GOTTO, Jr., MD, PhD

Lipid tests have to be interpreted on an individual basis by the patient's physician. The physician will want to take into account the family history, the physical examination and other laboratory tests. In making a diagnosis of primary hyperlipidemia, the physician has to exclude secondary causes of hypercholesterolemia or hyperlipidemia, to make sure that the patient does not have underlying nephrosis, liver disease, hypothyroidism or some other secondary problem. If the patient has primary hyperlipidemia, the next question is whether or not this is a familial type or other recognized hyperlipidemia, or a sporadic hyperlipidemia. Hypercholesterolemia may be of genetic basis, but not necessarily one of the commonly encountered hyperlipidemias, such as familial hypercholesterolemia. Over 90% of patients with hypercholesterolemia fall in the category of sporadic or polygenic etiology.

Another important consideration is the presence of given risk factors. The significance of a cholesterol level of 200 mg/dl depends on whether or not a person smokes cigarettes, has hypertension or has diabetes. A cholesterol level of 200 mg/dl in a diabetic patient who has hypertension and smokes is of much greater significance than a cholesterol of 200 mg/dl in a person who has none of the other risk factors.

The physician then has to decide whether or not a given level of cholesterol is too high, and, taking this and other clinical information into account, whether or not to begin treatment. If the cholesterol level is above moderate risk (>200 to 240 mg/dl), then the physician should undertake treatment. Treatment should begin with diet and, if the cholesterol level still remains elevated above the high risk level, drug therapy should definitely be added to diet therapy.

We also need to distinguish between those persons who are at high risk for coronary disease (on the basis of hypercholesterolemia and hyperlipidemia) and the general population. By high risk, I mean those persons at the upper end of the range of cholesterol levels. As far as the rest of the population is concerned, I agree with the position of the American Heart Association and the recommendation of the Cholesterol Consensus Conference Panel (see the article by Rifkind in this issue). That is, I believe the whole population needs to go on a diet with less fat, less saturated fat and less cholesterol to reduce cholesterol levels across the board. The American Heart Association has recommended that such a diet should be begun in everyone after the age of 2, and I agree with that general approach (Table I).

It is useful in terms of the overall population to consider the average level of cholesterol as it now exists, the ideal level of cholesterol and a feasible level of cholesterol. The average cholesterol level in the American population is about 215 to 220 mg/dl. The ideal level is ≤160 mg/dl. A feasible level would be approximately 190 mg/dl; this could be achieved if we could persuade the American population to go on phase 1 of the American Heart Association diet. In order to achieve these levels in adults, we have to intervene in childhood. If we strive to have an average cholesterol level of 180 to 190 mg/dl in adults, it is necessary to achieve an average cholesterol level of 160 mg/dl in children. Prevention across the board should be begun in childhood, after age 2, to achieve these objectives.

TABLE I Cholesterol-Lowering Diet with 3 Phases of Fat and Cholesterol Restriction

Phase	1	2	3
Fat (% calories)	30	25	20
Carbohydrate (% calories)	55	60	65
Protein (% calories)	15	15	15
Cholesterol (mg)	300	200–250	100–150
P/S (ratio polyunsaturated fat to saturated fat)	1	1	1–2

Interpreting Lipid Values in the Laboratory

GERALD R. COOPER, MD, PhD

Useful laboratory interpretation depends on 3 factors: a valid sample, an accurate method and a specific interpretation. A valid sample may be affected by a number of conditions. For example, precollection conditions are important. Among the circumstances that influence the precollection condition are the patient's life-style, diet, exercise and medication, especially diuretics. Intercurrent illness can also alter a patient's lipid levels; e.g., cholesterol levels drop dramatically in the weeks after a myocardial infarction.

Several factors that influence collection conditions deserve consideration. For example, if a person is recumbent for 20 minutes before a sample is taken, there can be a 15% change in the cholesterol value. If the tourniquet is applied too tightly for longer than 2 minutes, a change of 2 to 10% in the value can result. In addition, the anticoagulant used in the vacuum container can dramatically affect the sample. Heparin does not cause any difference between plasma or serum; however, versene causes a 3 to 5% difference. Oxalate creates an 8% difference, and citrate and fluoride can cause changes of as much as 12 and 18%, respectively. When using plasma, a full tube should always be collected. The source of the blood also affects the cholesterol level; there are differences between arterial and venous blood.

With regard to laboratory conditions, the measurement will be affected by the handling, storage and shipment of the specimen. In addition, the laboratory should have stable material with which to perform its analysis.

The enzymatic cholesterol and triglyceride methods are now widely used, accurate methods. Concern about incomplete hydrolysis, however, still exists. Complete hydrolysis must occur and results of the enzymatic method must agree with those of reference methods that yield true values. There are also problems involved in performing enzymatic triglyceride determinations. Correction for free glycerol is perhaps even more important. With respect to high density lipoprotein cholesterol methods, we must accept the fact that all the separation techniques yield different results in both high and low concentration specimens. I advise selecting 1 method, learning its problems and then specifically interpreting the results with respect to observed reference concentration and ratio ranges.

Finally, it is essential to develop specific interpretations to keep up with the development of accurate analytical methods. For the most part, laboratories and clinicians are not making sufficient use of the highly sophisticated methodology available. It is no longer acceptable to simply tell a patient that he is within a nonsensitive total cholesterol expected range of 150 to 250 mg/dl. Further, it would be helpful to the clinician if the laboratory could provide a percentile value that is normal to the observed population, as well as the absolute concentration value, of each patient's cholesterol determination.

In conclusion, there are 2 demands that must be made to ensure accurate test results. First, the clinician should demand that the laboratory give him an accurate result. Second, the laboratory director should demand that industry give laboratories reference materials, particularly calibration materials, that have been labeled accurately with reference methodologies. Together, these will do much to enhance the reliability of laboratory testing.

Discussion

Dr. Rifkind (Bethesda, Maryland): Dr. Gotto, you have stated that the dietary recommendations to the American people should be applied down to age 2, and that is not consistent with the recommendations of the American Heart Association and of the Consensus Conference. Earlier on, someone mentioned that reservations have been expressed about such dietary change in children. How do you respond to the criticisms that you have had regarding dietary fat restriction in childhood?

Dr. Gotto (Houston, Texas): I know of no evidence that the type of diet that we are talking about—30% calories of fat, 10% saturated, 10% polyunsaturated, 10% monounsaturated, with 250 to 300 mg of cholesterol and a balanced overall diet—is harmful to children or to adults. I think it is important to emphasize the fact that we are talking about a well-rounded, nutritious diet. The average person and many physicians think that we are talking about a very restricted diet. We are not. It is not impossible to provide such a diet—one with balanced meals, and food that is tasty and healthy at the same time. There are 2 reasons for starting such a diet as this: one is established and the other is theoretical. The established fact is that changing the dietary habits of the American population begins with children.

The second reason, the theoretical one, is that if we start such a diet earlier in life, we can possibly avoid the changes that occur by the time a person is 25 or 30 years old in our society, when some degree of coronary lesions can be detected. This has not been established experimentally, but I think at least it is a theoretical basis for adopting a diet.

Dr. LaRosa (Washington, D.C.): Dr. Gotto, you mentioned that relatively early in patient evaluation you would want to establish whether or not the patient has a genetic abnormality. For most practicing physicians, whose laboratory access may be limited to their local community or to a standard laboratory measurement, that sort of workup is either difficult or impossible. Is it important enough that such patients be referred somewhere else for evaluation? Do you feel that given our relatively limited ability, in terms of dietary and drug interventions, it is worth it to do that?

Dr. Gotto: I believe it is important to establish the lipoprotein type and whether the lipid disorder is familial, particularly the upper fifth percentile, where there is a much greater likelihood of identifying one of the well-recognized genetic forms of hyperlipidemia. For the group with cholesterol values in the upper twenty-fifth but below the fifth percentile, I think there is also some value in the work-up. For example, individuals affected with familial combined hyperlipidemia or familial multiple-lipoprotein-type hyperlipidemia may have only moderate elevations of cholesterol or triglyceride but have a greatly increased risk for early coronary disease.

When to refer a patient to a specialized center depends on the individual physician's confidence in the local laboratory, on his experience in dealing with these disorders and, to some extent, on his success. If he is able to put a patient on a diet and, if necessary, to start medication, and he gets a good response, then he does not need to refer the patient elsewhere. If on the other hand, he is unsuccessful, he may wish to consider referring the patient to a specialist.

While we have several drugs currently available, we would like to have a safe, effective agent that will lower total cholesterol and low density lipoprotein cholesterol by 50%.

Dr. Grundy (Dallas, Texas): Dr. Cooper, there have been some investigators who have suggested that if we could accurately measure the apoproteins we would have better indicators of risk. What is your judgment about that?

Dr. Cooper (Atlanta, Georgia): I think the potential for apoprotein measurements is great, but at the present time, the surveys indicate that a 75% error of measurements occurs between laboratories. There are problems of standardization and interpretation.

Dr. McManus (Omaha, Nebraska): I wanted to come back to Dr. Cooper's comments about reliability of lipid assays. We surveyed 121 academic clinical laboratories on questions pertinent to cholesterol. They were asked where they obtained their reference ranges for total serum cholesterol. The results highlight a fundamental problem that still exists with our best general blood test for coronary risk—total serum cholesterol. Even though there is substantial reference information available from the Centers for Disease Control and elsewhere, we found that of the 121 laboratories reporting, 17 based their reference range for cholesterol on a "local population", 15 on "healthy" people, 13 on a textbook, 12 on "unknown" publications, 10 on "manufacturers' inserts", 9 on "unspecified" patients and others on obscure bases, including venerable opinion. Two laboratories did not know where they obtained their cholesterol ranges. Thirty-seven laboratories did cite sources for reference ranges from published reports. I think these simple data pinpoint a problem in standardization.

A second message from the study is that of all the laboratories reporting, only 13 reported some kind of cutoff for total cholesterol values above which coronary risk was increased, 7 reported risk levels based on a total "lipid profile", 9 for a ratio of total cholesterol/high density lipoprotein cholesterol and another 6 for high density lipoprotein cholesterol alone. Three did it "informally"; i.e., the clinical laboratories contacted the clinical physician if the cholesterol value was considered too high. Finally, 3 laboratories said it was "the doctor's problem." I think there are very simple but pervasive information problems that need our attention in the attempts to better standardize laboratory reporting of lipid results.

Conclusions

SCOTT M. GRUNDY, MD, PhD

In recent years, several important advances have been made in the laboratory measurement of plasma lipids and lipoproteins. Perhaps the most important has been the introduction of enzymatic methods for the quantification of cholesterol and triglycerides. This approach has the potential for making highly precise measurements. The use of automated procedures combined with enzymatic measurements allows for the rapid processing of large numbers of samples. This capability provides a base for the broad screening of many patients for plasma lipids at a reasonable cost, and thus affords the opportunity for an active prevention program for the American population.

While total cholesterol measurements provide a good assessment of risk, laboratories must be able to accurately measure individual lipoproteins, including high density lipoprotein (HDL), low density lipoprotein and triglycerides. The accurate measurement of HDL cholesterol is particularly important. This measurement is needed to quantify cholesterol in the other lipoprotein fractions, and it also is needed to obtain an accurate estimate of total cholesterol/HDL cholesterol ratio. One of the major weaknesses of lipoprotein determinations in laboratories throughout the country appears to be in the measurement of HDL cholesterol. Different methodologies are used, and quality control needs to be improved.

This symposium considered reference ranges that should be used for total cholesterol and triglycerides in the American population. There was general agreement that the values outlined by the Consensus Conference on Lowering Blood Cholesterol to Prevent Heart Disease are reasonable. Table I provides a summary of the conclusions of the symposium with regard to risk categories for total cholesterol.

In evaluating patients with hyperlipidemia, it is important to simultaneously search for other risk factors—such as smoking, hypertension, diabetes mellitus and obesity. All of these factors significantly enhance the risk associated with any given level of cholesterol. For example, the risk for coronary artery disease (CAD) in a nonsmoker with a cholesterol level of 240 mg/dl is about twice that of a person with a baseline level of 200 mg/dl. In a smoker, in contrast, the risk is increased 4- to 6-fold above baseline. Thus, without the knowledge of other risk factors, an accurate assessment of the impact of plasma lipids and lipoproteins on coronary risk is not possible. All of these other factors accentuate the risk, and they heighten the importance of the plasma lipids and lipoproteins as risk factors for CAD.

Physicians who care for patients must learn how to interpret tests correctly, make clinical judgments about their patients and apply appropriate treatment on the basis of their findings, whether this treatment be the use of diets or drugs. We are very encouraged by the fact that there is a decline in the rates of CAD; careful analysis of this decline indicates that it is due in large part to modification of risk factors, including lowering of cholesterol, decrease in smoking and control of other risk factors in the U.S. population.

TABLE I Risk Categories Based on Plasma Total Cholesterol Levels

Risk Category	Plasma Cholesterol (middle-aged adults)	Population Percentile
Desirable range	<200 mg/dl	<40th
Mildly increased risk	200–240 mg/dl	40–75th
Moderately increased risk	240–265 mg/dl	75–95th
High risk	>265 mg/dl	>95th

The actual levels of plasma cholesterol shown are for middle-aged adults; the same percentiles hold for young adults, but the concentrations are lower.
